HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
A rhenium tris-carbonyl derivative as a single core multimodal probe for imaging (SCoMPI) combining infrared and luminescent properties

Sylvain Cléde,abc François Lambert,abc Christophe Sandt,d Zoher Gueroui,abe Matthieu Réfrégiers,d Marie-Aude Plamont,ff Paul Dumas,d Anne Vessieres,f and Clotilde Policar*abc

A rhenium tris-carbonyl derivative has been designed to couple infrared and luminescent detection in cells. Both spectroscopies are consistent with one another; they point out the reliability of the present SCoMPI (for Single Core Multimodal Probe for Imaging) for bimodal imaging and unambiguously indicate a localization at the Golgi apparatus in MDA-MB-231 breast cancer cells.

The variety of biological issues imposes the use of a wide range of techniques to understand and rationalize intricate biomolecular mechanisms. In this context, bio-imaging techniques are pivotal since they allow direct visualization of labelled biomolecules or organelles. Molecules or tags that can be detected by several complementary techniques offer possibilities of cross-correlative comparisons.1–3 Elaborate molecules showing dual properties, such as fluorescence and magnetic resonance4 or fluorescence and radio emission,5 have been designed and used as efficient reporters for cell and animal imaging. However, these derivatives are mostly multiple core entities where each covalently bound fragment plays a unique spectroscopic, magnetic or radioactive role,6 and whose large size is likely to modify the physico-chemical properties of the tagged molecule.

Fluorescence microscopy is a powerful, widespread technique for cell imaging. Many fluorophores are commercially available for organelle staining and biomolecule tagging. Turnkey filter-cubes adaptable to a large set of molecules allow quick and efficient detection of UV-visible fluorophores, which can also be observed in 3D using confocal fluorescence microscopy. Infrared spectroscopy involves weaker energies by probing only vibrational levels. Both radiation-induced damages and Rayleigh scattering (proportional to 1/l4) are weaker than in the UV-visible range. Since infrared wavelength absorption is specific for a given chemical bond, it allows chemical mapping of endogenous7,8 (amide, phosphate) and exogenous compounds such as metal-carbonyl derivatives.9–12 Interestingly, metal-carbonyl units have also been used in fluorescent cell-imaging.2,5,13–16 However, to our knowledge, multimodal detection involving both luminescence and infrared vibrational spectro- and microscopies has not been performed yet.

We show here that correlative studies can be efficiently carried out with multimodality arising from a unique molecular core—Single Core Multimodal Probe for Imaging, SCoMPI—namely, a single rhenium tris-carbonyl moiety (1, see Scheme 1) that has been designed to display infrared and luminescent properties, easily recognizable from endogenous cell response. This imaging approach indicates that 1 localizes to the Golgi apparatus of MDA-MB-231 cells.

Metal tris-carbonyl moieties (including Mn, Re, Os) have been used as IR-labels17 in few cases of subcellular mapping (IR or Raman).9–12 C3v local symmetry of M(CO)3 complexes induces two bands of absorption in the IR-transparency window of the cell: E-band (asymmetric stretching, doubly degenerate) at about 1920 cm−1 and A1-band (symmetric stretching) at about 2020 cm−1.18 These strong carbonyl absorptions previously allowed the mapping inside MDA-MB-231 breast cancer cells of an organometallic rhenium tris-carbonyl complex analogous to tamoxifen.11,19

To correlate IR chemical mappings with fluorescence microscopy, a mixed organometallic and coordination complex was designed as follows: the IR fragment was kept, as it was shown to be a reliable probe in biological media,11 and a 4-(2-pyridyl)-1,2,3-triazole ligand (or pyta) was introduced into the coordination...
sphere of rhenium. In similar complexes presenting low π*-orbitals on ligands, radiative metal-to-ligand charge transfer (MLCT) states are attainable upon excitation in the UV (about 330 nm) region and emit at around 520 nm. A lipophilic long alkyl side chain was introduced to encourage cellular uptake. Azide terminal function was added in order to compare infrared signals from N₃ and CO groups. Compound [ReCl(CO)₃-pyta-C₁₂N₃] I was synthesized as depicted in Scheme 1, using a “click-to-chelate” strategy. Its distribution in MDA-MB-231 breast cancer cells (incubation for 1 h at 37 °C in the 10-micromolar range; see ESI†) was studied using a bimodal approach: IR and luminescence imaging was performed, pointing out its localization to the Golgi apparatus.

IR spectra were recorded in the 1850–2200 cm⁻¹ range corresponding to the IR-transparency window of a typical eukaryotic cell. The FTIR spectrum of compound I (solid form, Fig. 1A-b) shows both E and A₁-bands characteristic of the Re(CO)₃ moiety, at 1920 and 2025 cm⁻¹, respectively, and a weak absorption at 2096 cm⁻¹ corresponding to the azide moiety. UV absorption bands at 300 nm have been assigned to intraligand π-π* transitions while the broad 320–350 nm absorption band is attributed to the MLCT transition (Fig. S1, ESI†). Irradiation in this band triggers a large radiative emission band at ca. 510 nm, characterized by a quantum yield of 0.19% in a water : ethanol (1 : 1) mixture at room temperature (Fig. 1B-c and Table S1, ESI†). Emission spectra (exc. 350 nm): (a) of a MDA-MB-231 single control cell, (b) of a MDA-MB-231 cell incubated with I (25 µM, 1 h), (c) of a 6.0 µM solution of I in water : ethanol (1 : 1). Spectra (a) and (b) recorded at the DISCO beamline (see ESI†).

IR-bands are displayed in Fig. 3. Hot spots of E and A₁-bands of I correspond to each other (Fig. 3c and d: E in red and A₁ in cyan respectively, and Fig. 3g: overlay in white), showing that it is possible to detect I in a single cell using either the E or A₁-band. Moreover, the radiative emission signal of I on the same cell (green area in Fig. 3e) matched the E and A₁-hot spots. These results provide evidence for the integrity of the bimodal core of I in an intracellular environment and the reliability of the bimodal IR and luminescence imaging.

Phosphate (asymmetric stretching, 1240 cm⁻¹, Fig. 3b, green) and amide (not shown) hot spots are colocalized and partly overlaid (Fig. 3f, yellow) with the E-band (red). As phosphate and amide hot spots are nucleus IR-signature, these IR-mappings also point out a spatial proximity between I and the nucleus. Although the resolution of SR-FTIR is...
diffraction limited (Abbe criteria, resolution of ca. λ/2) with a pixel set to 3 × 3 µm² these mappings are consistent with the fluorescence studies. Additional IR and luminescence mappings are presented in Fig. S4 (ESI†).

To confirm the attribution of the IR and fluorescent mappings to I, spectra have been recorded for a collection of cells (FTIR) or at the single-cell level (SR-FTIR and SR-UV-SMs). The IR-signals of I were observed in a FTIR spectrum of cells (ca. 41 000) incubated with I and deposited on the nitrocellulose membrane (Fig. 1A–c). The SR-FTIR-SM spectrum (Fig. 1A–d) was recorded for a single cell at the black cross shown in Fig. 3g. Both spectra matched that of the solid compound (Fig. 1A–b). Interestingly, the weak asymmetric stretching of the azide group at 2096 cm⁻¹ was also detected in the two cases (single cells and cell collection). None of these signals were found on control cells (Fig. 1A–a). As observed in IR spectroscopy, the fluorescence emission spectrum of cells incubated with I (Fig. 1B–b) matched that of the pure compound in solution (Fig. 1B–c) with interestingly weak cellular autofluorescence in the 480–540 nm range (considering the endogenous emission of control cells in Fig. 1B–a).

To investigate the perinuclear distribution of I, its accumulation in the Golgi apparatus was queried, since Golgi bodies are located close to the nuclear envelope. The Golgi apparatus is also known to be targeted by lipophilic derivatives, which is the case for I with its organometallic core and its long side chain. In addition, a localization in the Golgi apparatus has been previously suspected for a lipophilic rhenium tris-carbonyl orthophenanthroline complex coupled with biotin.

In Fig. 2, colocalization experiments using a Golgi tracker, the BODIPY® TR C₃-ceramide complexed to BSA, show an overlay (stretching) between I (green) and this tracker (red) with similar intensity profiles across the cell. Quantitative analyses strongly suggest the colocalization of I with the Golgi apparatus (Fig. 2: Pearson’s coefficient 0.93, overlap coefficient 0.96, intensity correlation quotient 0.41, see ESI†).

In conclusion, we report here the first successful bimodal subcellular imaging of a single core organometallic multimodal probe using both its infrared and luminescent signatures. The SCOMPI I, whose single metal-centered core combines both modalities, displays photophysical properties allowing its univocal detection in cells. Both spectromicroscopies are consistent with one another and show a perinuclear location of I that was assigned to the Golgi apparatus. Other metal–CO derivatives have been found to be accumulated in specific organelles, These various locations show that these probes can be delivered to different cell-compartments depending on their appended moiety, which is a valuable property for imaging applications.

Since infrared and luminescence spectroscopies are complementary for bio-detection and bio-imaging, IR-luminescent (L)Re(CO)₃ SCOMPIs are of great potential and their multiple modalities open up wide prospects for cross-correlative studies in biological media. IR bio-imaging is emerging, with potential applications at the tissue level. The elaboration of this small molecule chemistry to target organelles or tag molecules for imaging is likely to contribute substantially to our molecular-level understanding of chemical processes in cells.

ENS, CNRS (PIR-CNRS-PCV-prise de risque, UMR8640, 7203), UPMC-Paris 6 are acknowledged for financial support and ENS for SC’s PhD fellowship. We thank SOLEIL committee for beamtime (project 20100758).
