Abstract

In human crowds as well as in many animal societies, local interactions among individuals often give rise to self-organized collective organizations that offer functional benefits to the group. For instance, flows of pedestrians moving in opposite directions spontaneously segregate into lanes of uniform walking directions. This phenomenon is often referred to as a smart collective organization, as it increases the traffic efficiency without need of external control. However, the functional benefits of this emergent organization have never been experimentally measured, and the underlying behavioral mechanisms are poorly understood. In this work, we have studied this phenomenon under controlled laboratory conditions. We found that the traffic segregation exhibits structural instabilities characterized by the formation of organized and disorganized states, where the lifetime of well-organized clusters of pedestrians follow a stretched exponential relaxation process. Further analysis shows that the inter-pedestrian variability of comfortable walking speeds is a key variable at the origin of the observed traffic perturbations. We show that the collective benefit of the emerging pattern is maximized when all pedestrians walk at the average speed of the group. In practice, however, local interactions between slow- and fast-walking pedestrians trigger global breakdowns of organization, which reduce the collective and the individual payoff provided by the traffic segregation. This work is a step ahead toward the understanding of traffic self-organization in crowds, which turns out to be modulated by complex behavioral mechanisms that do not always maximize the group’s benefits. The quantitative understanding of crowd behaviors opens the way for designing bottom-up management strategies bound to promote the emergence of efficient collective behaviors in crowds.

Introduction

In many biological and social systems, such as fish schools, ant colonies, or human crowds, repeated local interactions among individuals support the emergence of a variety of collective patterns of motion [1–4]. Under certain conditions, the emerging organization allows the group to solve efficiently coordination problems without centralized planning or external control. In human crowds, such functional patterns of motion have been identified many times in the past, such as the alternating flows at a bottleneck [5], the formation of trails [6], or the walking configuration of social groups [7]. Remarkably, nobody orchestrates these phenomena and pedestrians do not actively seek these emerging collective organizations. Instead, individuals behave according to their own motivations, but local interactions generate functional organizations at the scale of the crowd. Therefore, these phenomena are often considered as prime examples of collective intelligence, sometimes called “the wisdom of crowds” [8–10].

One of the well-known example of such functional self-organization in crowds is the formation of lanes in bidirectional flows [11–13]: When two flows of pedestrians are moving in opposite directions in a crowded street, people spontaneously share the available space by forming a “pedestrian highway”, where individuals walking in opposite direction segregate into lanes. This self-organized pattern of motion enhances the traffic flow by reducing frictional effects, local accelerations, energy consumptions and walking delays [14].

According to previous modeling works, the formation of lanes goes along with a sudden transition from disorder (where individuals are randomly distributed) to order (where opposite flows are segregated) [3]. Similar transitions from disorder to order have been observed in a wide variety of complex systems composed of locally interacting agents, in physical [15,16], biological [2,17–19] and social systems [10,20,21]. In human crowds, however, little is known about this phenomenon. From an empirical and quantitative point of view, the features of the spontaneous traffic organization remain scarcely documented, and the behavioral mechanisms underlying this phenomenon are hardly understood. In fact, it is poorly known how the transition operates, how the traffic organization evolves in time, and how much this collective organization benefits to the group. In this work, we have investigated the dynamics of lane formation under laboratory conditions, and studied the benefits provided by this traffic organization at the individual and crowd levels. To study the formation of lanes under experimental conditions, one major issue arising from past works is to handle the participants’ inflow...
Author Summary

A crowd of pedestrians is a complex system that exhibits a rich variety of self-organized collective behaviors. For instance, when two flows of people are walking in opposite directions in a crowded street, pedestrians spontaneously share the available space by forming lanes of uniform walking directions. This “pedestrian highway” is a typical example of self-organized functional pattern, as it increases the traffic efficiency with no need of external control. In this work, we have conducted a series of laboratory experiments to determine the behavioral mechanisms underlying this pattern. In contrast to previous theoretical predictions, we found that the traffic organization actually alternates in time between well-organized and disorganized states. Our results demonstrate that this unstable dynamics is due to interactions between people walking faster and slower than the average speed of the crowd. While the traffic efficiency is maximized when everybody walks at the same speed, crowd heterogeneity reduces the collective benefits provided by the traffic segregation. This work is a step ahead in understanding the mechanisms of crowd self-organization, and opens the way for the elaboration of management strategies bound to promote smart collective behaviors.

without interfering with the phenomenon [13,22]. In fact, in a straight corridor, the starting positions of pedestrians regularly introduced from both ends strongly influence the resulting traffic organization, which is detrimental to the relevance of the measurements. To avoid this drawback, we have used a ring-shaped corridor that provides periodic boundary conditions [18,23]. In this way, observing the phenomenon without perturbations induced by the experimental procedure becomes possible. To observe the emergence and the temporal dynamics of lane formation, N participants were randomly distributed in the ring-shaped corridor. A walking direction was randomly attributed to each of them, in such a way that N/2 participants walked clockwise and N/2 anti-clockwise. At the starting signal, participants started to walk in their attributed direction, allowing us to observe and characterize the emergence of traffic organization. A total of 11 replications were analyzed, with N = 60, 50 and 30 participants (3, 2 and 6 replications, respectively).

In the following, we present our experimental results and show that the complex dynamics of traffic self-organization is based on simple behavioral mechanisms, where interactions between pedestrians walking faster and slower than the average trigger local perturbations that rapidly change into global traffic instabilities. While lane formation can be theoretically very efficient and functional, we show that, in practice, inter-individual variability undermines the overall benefits of the collective organization.

Results

Experimental results

Our experimental results reveal a rapid transition from disorder to order during the first moments of the experiment, where initially randomly located pedestrians self-organize into lanes of opposite walking direction [Fig. 1]. However, the ordered state displays instabilities, where the flow segregation vanishes after a certain time lap and reappears again later and so on. In order to characterize this unstable dynamics, we have elaborated a clustering method to identify groups of pedestrians walking in lanes [24] (see Materials and Methods). For this, we assume that a pedestrian j belongs to the same cluster as a pedestrian i if during a time period τ, j passes at a distance smaller than δ from the position of i at time t (see the sketch Fig. 2). It appears that the number of clusters decreases rapidly after the beginning of the experiment, but displays alternating phases of order (i.e. five clusters or less) and disorder (i.e. ten clusters or more) [Fig. 3]. To get a quantitative estimation of the traffic instability, we have measured the lifetime distribution of the clusters, where a cluster is considered as ‘dead’ when its composition changes by at least one individual. Fig. 4A shows the probability $p(t)$ for a cluster i to be alive t seconds after it appeared. As it can be seen, $p_i(t)$ decays very fast during the first 10 seconds of a cluster lifetime. Yet, some clusters remain stable for 30 seconds or more. Fig. 4B–C show that $p_i(t)$ decays slower than an exponential and faster than a power law. Fig. 4D shows that $p_i(t)$ can be fitted empirically to a stretched exponential relaxation law [25,26]: $p_i(t) = \alpha e^{-(t/t_0)^\beta}$, where $\alpha$ and $\beta$ are the relaxation parameters, and $t_0$ is the stretching exponent. The lifetime $t_0$ of a cluster can then be estimated by measuring the time after which a cluster has 95% chances to be changed by solving the equation $p_i(t_0) = 1 - 0.95$. Here, a numerical calculation gives $t_0 = 12.7(\pm 0.1), 8.4(\pm 0.2)$ and $7.8(\pm 0.2)$ seconds for N = 30, 50 and 60 pedestrians, respectively.

Having characterized the typical time scale of the traffic instabilities, we will now investigate the origin of this dynamics: What are the behavioral mechanisms underlying these instabilities? Further analysis of our data reveals important density fluctuations in the experimental corridor, where highly crowded zones and almost empty zones can be observed at the same moment of time in different areas of the corridor (see Video S3). Fig. 5A shows empirically measured density maps, representing the local density value $\rho(t)$ for all times t and in all directions $\theta$, as defined in the Materials and Methods section. The density maps illustrate the spontaneous emergence of density gaps and density peaks that propagate along the corridor. Moreover, we have measured in a similar way the local radial speed $v_r(\theta,t)$ of traffic organization, which measures the lateral movements of pedestrians (see Materials and Methods for a formal definition). In other words, $v_r(\theta,t)$ increases when pedestrians tend to move away from their lane, while it is close to zero when they walk one behind another. As shown in Fig. 5B, the place and time where the largest values of $v_r(\theta,t)$ occur coincide with the emergence of density gaps. In fact, Fig. 5C shows that the local radial speed is negatively correlated with the local density (a correlation test yields a p-value < 0.01 with a correlation coefficient $r = 0.3$, for all replications with N = 60 pedestrians, and after removing the first 10 seconds of the experiments). What is the origin of these density fluctuations, and why are they correlated with important lateral movements? First, density gaps can be interpreted as a consequence of the variability in the comfortable walking speed: as pedestrians do not walk exactly at the same speed, those moving faster catch up with those walking slower, leaving an empty zone in front of the slow walkers. Second, the occurrence of lateral movements around the density gap can be explained in a similar way: pedestrians who are willing to walk faster than others make use of density gaps to overtake the slow walkers in front of them. By doing so, faster pedestrians move away from their lane, and meet the opposite flow head-on a few seconds later. This initial perturbation often triggers a complex sequence of avoidance maneuvers that results in the observed global instabilities. Therefore, we hypothesize that traffic instabilities result from the pedestrians walking speed variability, where people walking slowly
Figure 1. Illustration of the unstable dynamics observed under experimental conditions for one replication with N = 60 pedestrians. Starting from a random initial state, the flows of pedestrians segregate after a short transition time (approximately 10 seconds in this replication). However, this ordered state turns to disorder after a certain period of time, before order emerges again later at the end of the experiment. (A) The upper figures are snapshots from the laboratory experiment, where people have been colored in red or blue according to their direction of motion. Blue pedestrians turn clockwise and red anti-clockwise. (B) The output of the tracking system with the same color-coding. (C) The average radial position $r_i$ of all pedestrians moving in the same direction, where the same color-coding is used. $R_{int}$ and $R_{ext}$ denote the internal and the external walls of the ring-shaped corridor. The alternation of mixed and segregated phases is visible. The transparent areas show the standard deviation of the mean value.

Figure 2. Illustration of the clustering method. (A) Two pedestrians $i$ and $j$ belong to the same cluster if one follows the other. (B) The pedestrian $j$ follows pedestrian $i$, if $j$ moves closer than a distance $\delta$ from the position of pedestrian $i$ at time $t$, during a time period of $\tau$ seconds. Here, $\tau = 1$ s and $\delta = 0.6$ m are two clustering parameters.

unintentionally create density gaps, and those walking fast make use of these gaps to overtake their neighbors, triggering a chain reaction that results in the observed traffic instabilities.

**Computer simulations**

In order to validate this hypothesis and better understand the system dynamics, we have conducted a series of computer simulations under the same experimental conditions. To investigate the effects of the inter-individual variability of walking speeds, the comfortable speed $v_0^i$ of simulated pedestrians is randomly chosen at the beginning of each simulation according to a Gaussian distribution with mean $\mu = 1.2$ m/s and standard deviation $\sigma$ that varies from 0 (i.e., homogenous crowd) to 0.3 (i.e., large inter-individual differences). These values were chosen consistently with our experimental results, where the control tests indicate that the participants comfortable walking speeds are normally distributed with mean $\mu = 1.2$ m/s and standard deviation $\sigma_0 = 0.16$ (Kolmogorov-Smirnov test: p-value = 0.73) (Fig. 6). Three examples of the dynamics observed during computer simulations are shown in Fig. 7.

By applying the clustering method defined above, we found that the clusters lifetime of simulated pedestrians also follow a stretched exponential relaxation law (Fig. 4.D). In particular, the relaxation exponents found in simulation are in good agreement with the experimentally determined ones. Furthermore, the simulation results indicate that the characteristic timescale of order phases decreases with increasing speed variability $\sigma$ (Fig. 8.A). Therefore, this supports our hypothesis that speed variability is responsible for the observed traffic instabilities. Interestingly, this unstable dynamics is very likely to reduce the overall benefits of lane formation. Therefore, we used the model to measure the collective and the individual benefits of the flow segregation with increasing heterogeneity in the crowd. For this, we measured the collective payoff $\beta$ of the traffic organization by comparing the actual traffic flow of pedestrians to the average value measured when the $N$ pedestrians move in the same direction: $\beta = (Q_+ + Q_-)/Q_0$, where $Q_+$ and $Q_-$ are the average flow of pedestrians moving in clockwise direction, anti-clockwise direction in the bidirectional situation, and $Q_0$ is the average flow in unidirectional situation at the same density level. Therefore, $\beta = 1$ when pedestrians reach a collective organization that minimize the friction effects due to the opposite flows, providing the same traffic quality as a unidirectional situation. While a homogeneous crowd maximizes the collective payoff by forming stable lanes, the occurrence of traffic instabilities for higher values of $\sigma$ notably reduces the quality of the traffic flow (Fig. 8.B). We also measured the individual payoff of a pedestrian $\pi_i = (v_i/v_0^i - 1)$, which reflects how much the pedestrian approaches its desired speed $v_0^i$ and desired direction.

---

**Figure 3.** (A) Illustration of the evolution of the number of clusters for three replications with $N = 30$, 50 and 60 pedestrians. The clustering method is described in the Materials and Methods section and illustrated Fig. 2. During the first ten seconds, the initial transition from disorder to order is visible. Then, the number of clusters oscillates between well-organized (five clusters or less), and disorganized states (ten clusters or more). (B) The corresponding segregation dynamics for the same three replications. doi:10.1371/journal.pcbi.1002442.g003
As shown in Figure 8, pedestrians who try to walk faster than the average have the lowest individual payoff, while those walking slower have the highest level of satisfaction. However, their combined effects have an important influence on the overall dynamics. In fact, even pedestrians who “cooperate” (i.e., those who have a desired speed close to the average) are increasingly less satisfied as the crowd becomes more heterogeneous, due to the strongest traffic instabilities induced by those who do not cooperate.

### Discussion

The spontaneous traffic organization of pedestrian flows is a functional self-organized collective pattern in human crowds, where people spontaneously share the available space by forming lanes of uniform walking direction. Based on experimental measurements, we found that this phenomenon exhibits structural instabilities, where mixed and well-segregated phases alternate in time. Our study demonstrates that speed variability among individuals is a key element underlying the observed traffic perturbations. Previous modeling work have suggested a similar relation between traffic stability and the fluctuations or heterogeneity of the system, but these results were based on numerical simulations only [27,28]. In particular, our data allowed us to unravel the precise mechanisms underlying the emergence of traffic perturbations: people walking slower create density gaps, while those walking faster make use of these gaps to overtake other pedestrians in front of them. These specific local interactions finally result in large-scale traffic breakdowns, and the spontaneous self-organization ends up in a sub-optimal state. Therefore, the collective payoff of the group is undermined because pedestrians try to increase their individual level of satisfaction. Indeed, it is known that walking at the comfortable walking speed provides individual metabolic-related benefits [29]. But even pedestrians who cooperate by walking at the average group speed are increasingly less satisfied as other individuals deviating from the average speed are numerous. This incompatibility between individuals’ satisfaction and crowd payoff is typical of many social dilemmas where self-interest conflicts with group interest [30,31].

Nevertheless, the functional benefit of traffic segregation is maximized in homogeneous crowds. Only diversity reduces the efficiency of the spatial self-organization. Many other decentralized systems facing coordination problems display the same trend. In car traffic, the variability among drivers’ behaviors also lead to disturbing collective patterns, such as stop-and-go waves and large-scale traffic jams [9,32,33]. In other biological systems such as animal swarms, goal oriented collective motion is also disturbed by the presence of inter-individual variability [18,34]. Remarkably, when facing other kinds of tasks, inter-individual variability may have the opposite effect and promote the emergence of efficient behaviors [35–37]. In collective decision-making problems, heterogeneity favors the discovery of new solutions and prevents the group from staying stuck in suboptimal behaviors [38,39]. Therefore, it seems that group diversity can either promote or disturb collective intelligence depending on the nature of the task.

Among the rich variety of self-organized collective behaviors observed in human crowds, not all of them offer functional benefits to the group. While some phenomena like traffic segregation, or alternating flows at bottlenecks provide decentralized solutions to deal with congestion situations, other collective behaviors such as stop-and-go waves or crowd turbulence lead to serious traffic perturbation that may have life-threatening effects [40].
Self-Organized Walking Patterns in Human Crowds

fore, understanding the mechanisms underlying these collective behaviors would open the way for the design of bottom-up management strategies bound to promote smart collective behaviors and minimize the risks during mass events. Our results already suggest real-life applications to enhance traffic efficiency and walking comfort in crowded walkways. For instance, dividing the pavement into a “fast lane” and a “slow lane” would reduce the overall speed variability in the crowd, and therefore avoid the emergence of traffic breakdowns. This appears to be particularly suited to crowded pedestrian walkways in large cities, where local commuters often meet up with foreign tourists. In the future, insights about pedestrian crowds may also serve as a basis for the

Figure 5. Correlation between local radial speed and density gaps. (A) Local density maps $\rho(h,t)$ for three representative replications with $N=30, 50$ and $60$ pedestrians. The emergence and the propagation of density peaks (red) and density gaps (blue) are visible. (B) Local radial speed $v_n(h,t)$ for the same three replications, showing the lateral movements of pedestrians. The largest values occur mostly around density gaps. (C) Average local density as a function of local radial speed, for all replications with $N=30, 50$ and $60$ pedestrians. The largest values of $v_n(h,t)$ occur where the local density level is low, that is, around density gaps. This correlation is less visible for $N=30$, probably due to the lower global density level.

investigation of other kinds of crowds, such as groups of web users, traders at stock market, or consumers [21,26,30,31].

Materials and Methods

Experimental design

Controlled experiments were conducted in May 2009 at the INRIA in Rennes, France. The goal was to observe the emergence of spontaneous traffic organization in bidirectional flows of walking pedestrians. A total of 119 participants took part in the study, which conformed to the Declaration of Helsinki. They were naïve to the purpose of our experiments, and gave written and informed consent to the experimental procedure. None had known pathology that would affect their locomotion. Experiments were conducted in a ring-shaped corridor with inner radius \( R_{in} = 2 \) m and outer radius \( R_{out} = 4.5 \) m, providing a total surface of 51.05 m

\[^2\] (see Fig. 1) built in a larger experimental room. As a control experiment, each participant was first instructed to walk alone in the experimental corridor (see Video S1). Then, we studied the effect of pedestrian density on the emergence of collective patterns of motion. Experimental trials were made with \( N = 30, 50 \) and \( 60 \) pedestrians, corresponding to a global density level of 0.59, 0.98 and 1.18 p/m

\[^2\], respectively. A total of 3, 2 and 6 replications were reconstructed and analyzed for \( N = 60, 50 \) and \( 30 \) participants, respectively. At the beginning of each trial, \( N \) participants were randomly distributed in the experimental corridor, and a walking direction was randomly attributed to each of them, in such a way that \( N/2 \) participants walked clockwise and \( N/2 \) anti-clockwise. At the starting signal, participants were asked to walk in their attributed direction as if they were moving alone in a street, and were not allowed to talk to each other (see Video S1). Each replication lasted for 60 seconds.

The motion of each participant was recorded by means of an optoelectronic motion capture system (VICON MX-40, Oxford Metrics, UK). Participants were equipped with a white T-shirt and 4 reflexive markers, one on the forehead, one on the left acromion, and two on the right acromion to easily distinguish the left shoulder from right one. Markers motion was reconstructed using Vicon IQ software. The location of each participant was finally described as the center of mass of the 4 markers projected onto the horizontal plane (see Video S2).

Clustering method

Two pedestrians belong to the same cluster at a given moment of time if one of them is following the other. We assume that a pedestrian \( j \) is following another pedestrian \( i \) at time \( t \), if the trajectory of \( j \) in the time segment \( t \to t+\tau \) passes at a distance smaller than \( \delta \) from the location of pedestrian \( i \) at time \( t \). This definition of the clustering method is illustrated in Fig. 2. The distance threshold was set to \( \delta = 0.7m \) and the time window length was set to \( \tau = 1s \). In the supporting information it is shown that the parameter values do not significantly affect the clustering outcome, as long as these lie in a reasonable interval (see Text S1, Fig. S1 and Fig. S2).

Simulation model

Simulations were performed by means of the previously published heuristics-based model for pedestrian behavior [3]. The model describes the adaptation of the actual velocity \( \vec{v}_i \) of pedestrian \( i \) at time \( t \) by the acceleration equation \( \dot{\vec{v}}_i = (\vec{v}_{des} - \vec{v}_i)/\tau \), where \( \tau \) is the relaxation time of 0.5 seconds, and the vector \( \vec{v}_{des} \) is the desired velocity pointing in direction \( \vec{a}_{des} \) and has the norm \( ||\vec{v}_{des}|| = v_{des} \). The desired direction \( \vec{a}_{des} \) is given by minimizing the distance \( d(z) \) to the destination:

![Figure 7. Illustration of the dynamics observed during computer simulations.](image-url)
where \( x_0 \) is the direction of the destination point \( O_i \) and the function \( f(x) \) is the distance to the first collision if pedestrian \( i \) moved in direction \( x \) at his comfortable walking speed \( v_0^i \), taking into account the other pedestrians’ walking speeds and body sizes. For simplicity, we represent the pedestrian’s body by a circle of radius \( R_i \). If no collision is expected to occur in direction \( x \), \( f(x) \) is set to a default maximum value \( d_{\text{max}} \), which represents the “horizon distance” of pedestrian \( i \). The direction \( x \) is bounded by the vision field of the pedestrian, which ranges to the left and to the right by \( \phi \) degrees with respect to looking direction \( H_i \).

The desired velocity is given by the equation \( v_{\text{des}}(t) = \min(v_0^i, d_h/t) \), where \( d_h \) is the distance between pedestrian \( i \) and the first obstacle in the desired direction \( x_{\text{des}} \) at time \( t \).

In cases of overcrowding, physical interactions between bodies may occur, causing unintentional movements that are not determined by the above heuristics. Therefore, in situations where the pedestrian \( i \) would be in physical contacts with other pedestrians, a repulsive force is used instead \( f_{ij} = kg(R_i + R_j - d_{ij})\hat{w}_{ij} \), where \( g(s/j) \) is zero if the pedestrians \( i \) and \( j \) do not touch each other, and otherwise equals the argument \( s \). \( \hat{w}_{ij} \) is the normalized vector pointing from pedestrian \( j \) to \( i \). The physical interaction with a wall \( W \) is represented analogously by a contact force \( f_{iW} = kg(R_i - d_{iW})\hat{n}_{iW} \), where \( d_{iW} \) is the distance to the wall \( W \) and
\( \mathbf{n}_{iw} \) is the direction perpendicular to it. Here again, the contact force with walls vanishes when the pedestrian does not touch the wall. The resulting acceleration then reads

\[
d\mathbf{v}_i/dt = \sum_j f_{ij}/m_i + \sum_w f_{iw}/m_i \]

and is solved together with the usual equation of motion \( d\mathbf{x}_i/dt = \mathbf{v}_i \), where \( \mathbf{x}_i(t) \) denotes the location of pedestrian \( i \) at time \( t \).

In order to simulate the movement of a pedestrian turning in the ring-shaped corridor, the destination point \( \mathbf{d}_o \) is updated at each simulation time step and located at a distance \( d_o = 5 \) meters away from the ring tangent to the ring radius. The value of \( d_o \) has been determined based on the control experiment results, by varying \( d_o \) from 3 to 10 and choosing the value that minimizes the deviation between observed and predicted trajectories. The simulation parameters are \( \tau = 0.5 \) s, \( \phi = 45^\circ \), \( d_{\text{max}} = 10 \) m, \( k = 10^3 \), \( R = 0.2 \) m.

**Measurement functions**

The local density \( \rho(x,t) \) at time \( t \) and in direction \( \theta \) is defined as the average value of the local density \( \rho(x,t) \), for all points \( x \) of the corridor located along the direction \( \theta \) (with a reasonable spatial resolution). The local density is defined according to Ref. [40] as \( \rho(x,t) = \sum d_{ij} \), where \( d_{ij} \) is the distance between the center of mass of pedestrian \( j \) and location \( x \), and \( f(d) \) is a Gaussian-based weight function \( f(d) = \frac{1}{\sqrt{2\pi}d_o} \exp(-d^2/d_o^2) \). The weight parameter \( R \) is set to \( 0.7 \) m.

The local radial speed \( v_r(\theta,t) \) is defined as the average radial speed \( v_i \) of all pedestrians \( i \) located between directions \( \theta_1 \) and \( \theta_2 \) at time \( t \), where the parameter \( \Delta \theta \) is set to \( \pi/16 \). The radial speed \( v_r \) is given by \( \mathbf{v}_r = \mathbf{R} \mathbf{f}_r/\Delta t \), where \( r_j \) is the radial position of pedestrian \( j \) in the experimental step.
