List of non-standard abbreviations: AMPK, AMP-dependent kinase ; Atg, autophagy-related gene ; DAMP, damage-associated molecular pattern molecules ; DAPK1, Death-associated protein kinase 1 ; ER, endoplasmic reticulum ; HDAC, histone deacetylase ; HIF-1, hypoxia-inducible factor-1 ; HMGB1, high-mobility group box 1 ; mTOR, mammalian target of rapamycin ; PTEN, phosphatase and tensin homolog ; RAGE, receptor for advanced glycation endproducts ; ROS, reactive oxygen species ; TSC2, tuberous sclerosis protein 2 ; ULK, Unc-151-like kinase ; UVRAG, ultraviolet radiation resistance associated gene

Abstract

1
2
3 Since the 1940's, chemotherapy has been the treatment of choice for metastatic disease.
4
5 Chemotherapeutic agents target proliferating cells, inducing cell death. For most of the history
6
7 of chemotherapy, apoptosis was thought to be the only mechanism of drug-induced cell death.
8
9 More recently, a second type of cell death pathway has emerged: autophagy, also called
10
11 programmed type II cell death. Autophagy is a tightly-regulated process by which selected
12
13 components of a cell are degraded. It primarily functions as a cell survival adaptive
14
15 mechanism during stress conditions. However, persistent stress can also promote extensive
16
17 autophagy, leading to cell death, hence its name. Alterations in the autophagy pathway have
18
19 been described in cancer cells that suggest a tumor-suppressive function in early
20
21 tumorigenesis, but a tumor-promoting function in established tumors. Moreover,
22
23 accumulating data indicate a role for autophagy in chemotherapy-induced cancer cell death.
24
25 Here, we discuss some of the evidence showing autophagy-dependent cell death induced by
26
27 anti-neoplastic agents in different cancer models. On the other hand, in some other examples,
28
29 autophagy dampens treatment efficacy, hence providing a therapeutic target to enhance cancer
30
31 cell killing. In this paper, we propose a putative mechanism that could reconcile these two
32
33 opposite observations.

1 In the unremitting fight against cancer, chemotherapies are one of the major tools that
2 oncologists used to treat and cure patients, especially if a metastatic disease is diagnosed.
3
4 Nitrogen mustards and antifolate agents were the first molecules to be used before the
5
6 emergence of DNA-damaging agents and microtubule targeting drugs. Targeted therapy,
7
8 based on specific alterations of cancer cells, is the next frontier in chemotherapy, [1-3].
9
10 However, the main objective of all of these approaches is to kill cancer cells.
11
12
13
14

15 For years, apoptosis was thought to be the principal mechanism by which chemotherapeutic
16
17 agents kill cells. Apoptosis is a programmed cell death highly conserved that regulates the
18
19 tissue homeostasis and/or eliminate damaged and infected cells. Two major apoptotic
20
21 pathways exist: the extrinsic pathway mediated by death receptors and the intrinsic pathway
22
23 mediated by mitochondria. These apoptotic signaling pathways lead to an important event: the
24
25 activation of caspases, cysteine proteases that cleave different substrates eventually leading in
26
27 cell dismantling.
28
29
30
31

32
33 Accumulating evidence now shows that anticancer agents also elicit other forms of non-
34
35 apoptotic cell death including necrosis, mitotic catastrophe, autophagy and senescence [4-6].
36
37
38 Furthermore, a continuum exists between apoptosis and necrosis, depending, for example, on
39
40 the concentration of the chemotherapy agent that the cancer cells are exposed to. Necrosis has
41
42 been viewed as a form of accidental cell death brought by injury. Recent findings have
43
44 suggested that some forms of necrosis are programmed; this process has been called
45
46 necroptosis. In addition, autophagic and apoptotic features can be observed in the very same
47
48 cell. Altogether, this leads to a complex wiring of cell death and survival networks that finally
49
50 tilts cell fate towards death or life. The purpose of this review is to focus on the role of
51
52 autophagy in anticancer agent-induced cell death.

Autophagy is a self-degradative process that enables cells to cope with stresses such as nutrient deprivation, ER stress, pathogen infection or hypoxia. Autophagy is thus generally considered to be a survival mechanism. On the other hand, when the severity or the duration of the stress is too long, or in apoptotic-deficient cells, autophagy may participate in cell death. Therefore, it has been called type II programmed cell death (type I being apoptosis itself). The role of autophagy in cell demise was first proposed because a large number of autophagic vacuoles have been observed in dying cells from various animal species. This was thought to mainly occur during the developmental program (e.g. in salivary glands in *Drosophila*) or during homeostatic processes (e.g. during organ involution). More recent data have demonstrated autophagic features in cells treated with chemotherapeutic agents (see below). The question, “Is autophagy an innocent bystander, a direct cell death execution pathway, a defense mechanism that ultimately fails in its mission to preserve cell viability and/or a garbage disposal mechanism that cleans up remnants of a cell already committed to die” [7] still needs clarification. All may be true according to the circumstances.

There are three types of autophagy, all of which promote degradation of cytosolic components but differ in their mechanisms and functions: micro-autophagy, chaperone-mediated autophagy and (macro)-autophagy, which is the one considered in this review. Autophagy delivers portions of the cytosol, possibly including organelle(s), to the lysosome via its inclusion in a double membrane vesicle. The fusion of this vesicle with the lysosome permits the hydrolysis of its contents by the lysosomal acidic hydrolases. Permeases and transporters then export amino acids and other biomolecules into the cytosol where they can be reused for cell metabolism and synthesis. Through this process, autophagy provides building blocks in the event of nutrient deprivation and helps cells to sustain stresses. A specific form of macro-autophagy is mitophagy, a process by which damaged mitochondria are degraded.

1
2 Mechanisms inducing mitophagy involve the PTEN-induced putative kinase protein 1
3 (PINK1) and the E3 ubiquitin ligase, parkin.
4

5 Autophagy is a highly regulated process consisting of induction, cargo selection and
6 recognition and vesicle formation, which produces the autophagosome that then fuses with a
7 lysosome. Several signaling pathways that initiate autophagy converge at one serine/threonine
8 protein kinase, mTOR (mammalian Target Of Rapamycin). The energy sensor AMPK (AMP-
9 dependent Kinase) is such an example. mTOR negatively regulates Atg1 (AuTophagy related
10 Gene 1) or its mammalian homologs, ULK-1 and -2 (Unc-151-like kinase) in nutrient rich
11 conditions, thus inhibiting autophagy [8]. Different sets of Atg proteins comprise the core of
12 the autophagy machinery and are then involved in the next successive steps [9, 10]. Of note is
13 the role played by Beclin-1, a member of the Bcl-2 family. Beclin-1 is the mammalian
14 homolog of the yeast Atg6 gene. When released from Bcl-2 at the level of the endoplasmic
15 reticulum, Beclin-1 associates with the class III phosphatidylinositol 3-kinase Vps34,
16 UVRAG (ultraviolet radiation resistance associated gene), and other partners that are
17 required, in addition to the ULKs, for autophagy vesicle nucleation [11, 12]. The next step in
18 autophagophore elongation requires two ubiquitin-like systems: the first aims to conjugate
19 Atg5 to ubiquitin-like Atg12 via the E1- and E2-like activities of Atg7 and Atg10,
20 respectively. Atg5-Atg12 conjugates oligomerize and localize at the outer membrane of the
21 expanding membrane. The second system links Atg8 (also called LC3) that has been cleaved
22 by Atg4 to phosphatidylethanolamine, which leads to LC3-II isoform. LC3-II is then recruited
23 both at the inner and the outer membranes of the growing vesicle. Both complexes are
24 required for membrane elongation and fusion leading to a closed vesicle. The completion of
25 the autophagosome is followed by its fusion with a lysosome [8].

57 2. Role of autophagy in cancer

58
59
60
61
62
63
64
65

1 Alterations in the autophagy pathway in cancer cells raised a paradox because autophagy
2 functions as a tumor suppressive mechanism, but is also used by cancer cells for
3 cytoprotection to cope with their hostile microenvironment [13-15]. This dual role of
4 autophagy in tumor development is illustrated by the fact that colorectal cancer patients with
5 extensive over- or underexpression of Beclin-1 have a much poorer overall survival [16].
6
7
8
9

10 11 12 *2.1 Tumor suppressive functions of autophagy* 13 14 15

16 The first evidence that autophagy is tumor suppressive came from the observation that Beclin-
17 1 haplodeficient mice suffered from a high incidence of spontaneous tumors [17]. Beclin-1
18 down-regulation is also required for malignant transformation induced by oncogenic ras [18].
19
20 Furthermore, its expression is frequently decreased in human breast cancers [19] as well as in
21 melanomas [20]. Both genetic and epigenetic silencing of the Beclin-1 gene has been shown
22 in human breast tumors [21]. Combined decreased expression of Beclin-1 and LC-3 is also
23 observed in human glioblastomas [22]. Alteration in other autophagy-involved genes has also
24 been reported in different tumor types: this has been observed for Atg5 in a natural killer-
25 specific leukemia [23], for UVRAG in colorectal and gastric carcinomas [24, 25], for Atg4C
26 in KO mice that developed fibrosarcomas induced by methylcholanthrene [26] and for Bif-1
27 in human pancreatic ductal adenocarcinoma [27]. It has also to be mentioned that
28 hyperactivation of the Akt pathway is observed in numerous cancer types, which positively
29 regulates cell proliferation and survival while inhibiting autophagy through the activation of
30 mTOR. Activating mutations of mTOR have recently been discovered in tumors that would
31 also result in autophagy downregulation [28].

52 At least three mechanisms have been proposed to explain the tumor-suppressive function of
53 autophagy. The first one is that autophagy eliminates damaged organelles that may produce
54 high amounts of ROS (reactive oxygen species) and hence limits chromosomal instability

65

1 [29]. Another consequence of autophagy is the elimination of p62, preventing the signal
2 transduction adaptor function of p62 in pathways critical for oncogenesis [30]. A third
3 mechanism would be to prevent cell necrosis in response to metabolic stress. Indeed,
4 inflammatory cells infiltrate tumors in necrotic areas that then favor tumor growth [31]. Taken
5 together, these observations suggest that basal autophagy is protective against cell
6 transformation, i.e. in the early phase of tumorigenesis.

Later, as tumors grow, cancer cells may need autophagy to survive their nutrient-limited and low-oxygen microenvironment, especially in the inner region of the tumor that is poorly vascularized. This ability to cope with stress is also useful to cancer cells that disseminate and metastasize [32]. Indeed, cell detachment from the extracellular matrix initiates a form of cell death that is called anoikis. Tumor cells must overcome anoikis in order to survive the invasion of blood fluid, and autophagy is one way of doing this [33]. This has been demonstrated using breast cancer cells in vitro [34]. Data obtained from patients with colorectal adenocarcinoma indeed showed a correlation between high LC3 accumulation with metastasis and poor prognosis [35]. The precise function of detachment-induced autophagy resulting in enhanced cell survival remains currently unclear. One possibility would be that, similar to its role in starvation, autophagy may compensate for the loss of extrinsic signals that normally occur through integrins, promoting nutrient and energy metabolism. Mechanistically, autophagy is induced via persistent activation of AMPK and eukaryotic initiation factor-2 α , both being inhibitors of mTOR [33].

Recently a new hypothesis has been proposed to resolve the apparent autophagy paradox in cancer: the “autophagic tumor stroma model of cancer cell metabolism,” in which cancer cells used ROS to signal stromal cells to undergo autophagy, fueling them with nutrients [36].

1 Autophagy in the tumor stroma thus serves as a “battery” for energy transfer, in the form of
2 recycled chemical building blocks, as well as lactate, to the highly proliferative cancer cells.
3
4 To what extent this process really participates in tumor growth still needs to be evaluated.
5
6

7 3. Role of autophagy in regulating anticancer agent-induced cell death

8 *3.1 Balance between apoptosis and autophagy for inducing cell death*

9
10
11 In their revised version of the hallmarks of cancer, Hanahan and Weinberg added other types
12 of cell death beyond the previously described apoptosis. In this regard, autophagy as well as
13 necrosis are seen as contributing to and/or counteracting drug-induced apoptosis and cell
14 death [37]. Complex crosstalk between apoptosis and autophagy has been unraveled. There is
15 substantial evidence indicating that suppression of apoptosis induces autophagy, while
16 autophagy inhibition causes apoptosis [38, 39]. On the other hand, sometimes autophagy and
17 apoptosis are triggered by a common upstream signal, suggesting at least one shared
18 molecular switch. Beclin-1 is certainly a major player in this interplay [40]. This dual
19 exclusive or cooperative interplay is well illustrated when the response of cancer cells to
20 chemotherapy is investigated. Indeed, according to the drug and the cancer cell type, there are
21 as many examples of a lethal effect of autophagy induction as examples of its anti-apoptotic,
22 hence pro-survival, influence.

44 Few reports address the mechanisms by which chemotherapeutic agents trigger autophagy.
45 These mechanisms may differ according to the type of drugs used, such as DNA-damaging
46 agents, microtubule interfering molecules, kinase inhibitors, etc. One common pathway is the
47 activation of p53; p53 then transcriptionally increases the expression of proteins involved in
48 positively regulating the autophagy pathway. This is the case for AMPK, DAPK1 (Death-
49 associated protein kinase 1), TSC2 (tuberous sclerosis protein), ULK1/2, and sestrin 1/2 [41].
50
51
52
53
54
55
56
57
58
59 Other pathways involve activation of JNK, which induces Beclin-1 release from its inhibitory
60
61
62
63
64
65

1 interaction with Bcl-2 at the level of the ER, through phosphorylation of the latter; increased
2 Beclin-1 expression; increased level of VMP1 (vacuole membrane protein 1), which is a
3 protein that interacts with Beclin-1 to regulate the Vps34 lipid kinase activity; inhibition of
4 class I phosphatidyl inositol 3-kinases, which in turn inhibit mTOR; and activation of class III
5 phosphatidyl inositol 3-kinases such as Vps34. The extent of their implications in different
6 conditions and/or according to the cell type, their putative cooperation and the way they are
7 actually initiated still need to be clarified. What also needs to be addressed is the question of
8 whether the final outcome, death or survival, is influenced by the pathway through which
9 autophagy is induced.

20
21

22 *3.2 Death inducing contribution of autophagy*

23
24
25 Various anticancer chemotherapies have been shown to induce autophagy, which in
26 cooperation with apoptosis participates in the induction of cell death. In some cases, intact
27 autophagy machinery is even required to induce cell death. Such a death-promoting effect has
28 been described for a large variety of drugs in different cancer cell types. The first examples
29 are for DNA-damaging agents in cell models in which autophagy is inhibited either by
30 pharmacological inhibitors like 3-methyladenine or by the use of siRNA targeting Beclin-1,
31 Atg5 or Atg7: hepatoma cells [42] or cervical carcinoma cells [43] exposed to etoposide,
32 papillary thyroid cancer cells [44] or different sarcoma cell lines [45] incubated with
33 doxorubin, cervical cancer SiHa cells exposed to carboplatin [46] or pancreatic cancer cells
34 treated with gemcitabine [47]. Autophagy also contributes to cell death induced by
35 microtubule targeting agents like paclitaxel [48, 49] as well as by the new “smart” drugs. The
36 cytotoxicity induced by imatinib, an inhibitor of the tyrosine kinase activity of growth factor
37 receptors, is decreased if autophagy is inhibited in human early stage malignant glioma cells
38 [50]. Autophagic cell death is also induced in different cancer cell lines by HDAC (histone
39 deacetylase) inhibitors [51]. Moreover, cell death is achieved by activating the autophagy
40
41
42
43
44
45
46
47
48
49
50
51

60
61
62
63
64
65

1 pathway in cells that respond by weak apoptosis to cetuximab, a monoclonal antibody
2 targeting the EGF receptor [52]. These different observations show that autophagy takes part
3
4 in cell death induction in apoptosis competent cells while it becomes the major death-
5
6 inducing pathway in apoptosis deficient cells.
7
8
9

10 Tumor hypoxia has been demonstrated to affect treatment outcome both in vitro and in vivo
11
12 [53, 54]. Several mechanisms explain this resistance; the main one is suppression of
13
14 apoptosis, primarily due to the activation of the transcription factor HIF-1 (hypoxia-inducible
15
16 factor-1) [55]. However, since more and more reports showed that autophagy participates in
17
18 chemotherapeutic agent-induced cell death, the influence of hypoxia on autophagy in cells
19
20 exposed to anticancer drugs has begun to be investigated as well. Two different effects have
21
22 been shown: either hypoxia modifies the cytotoxic consequences of autophagy activation
23
24 towards a pro-survival influence, as observed in HepG2 cells exposed to etoposide [42], or
25
26 hypoxia itself induces autophagy, without being triggered by the drug, and this autophagy
27
28 process is coupled with the blockage of apoptosis, thus preventing cell death. This has been
29
30 observed in vitro in hepatocellular carcinoma cells [56] and in HeLa cells [57] as well as in
31
32 vivo in murine models of head and neck squamous cell carcinomas [58]. The severity and/or
33
34 the duration of hypoxia may tilt the balance toward one or the other, as already observed for
35
36 apoptosis [59].
37
38
39
40
41
42
43
44

45 *3.3 Cytoprotective effect of autophagy*

46
47

48 Autophagy enables cancer cells to survive the harsh conditions of their microenvironment,
49
50 while also enabling them to sustain chemotherapy thus conferring resistance. High level of
51
52 autophagy detected in cells exposed to anticancer agents signifies an adaptive response [60].
53
54 This has been demonstrated by showing that autophagy inhibition synergizes with
55
56 chemotherapeutic agents to more efficiently kill cancer cells in numerous cancer cell types
57
58
59
60
61
62
63
64
65

1 exposed to various drugs. The reasons why, in some cases, autophagy participates to cell
2 death while in others, it prevents it, are not understood, especially since both effects can be
3
4 observed within the same anticancer molecule. Examples for a key role of autophagy in
5
6 chemoresistance are numerous when DNA damaging agents are used: camptothecin in breast
7
8 cancer cells [61]; cisplatin in esophageal squamous cell carcinoma cells [62], in metastatic
9
10 skin carcinomas [63] and in lung adenocarcinoma cells [64]; and 5-fluorouracil in colon
11
12 cancer cells [65] and in esophageal cancer cells [66]. Similar observations were obtained with
13
14 the new generation drugs: proteasome inhibitors [67, 68], Src kinase inhibitor [69] and anti-
15
16 HER2 monoclonal antibody [70] are such examples.
17
18
19
20
21

22 The mechanism by which autophagy inhibition relieves resistance is often due to a shift
23
24 toward apoptotic cell death. It has to be mentioned that cell crosstalk initiated by a dying cell
25
26 induces autophagy in adjacent cells that renders them resistant to therapy. Dying cells release
27
28 damage-associated molecular pattern molecules (DAMP), among which is HMGB1 (high-
29
30 mobility group box 1). This protein interacts with the surface of other cells via the RAGE
31
32 receptor (Receptor for Advanced Glycation Endproducts) and induces autophagy and drug
33
34 resistance (Figure 1). This dialogue has been demonstrated in leukemia cells [71, 72].
35
36
37
38
39
40 Whether such a process occurs in other types of cancer remains to be determined.
41
42

43 4. Targeting autophagy as a new anticancer therapeutic approach

44 *4.1 To provoke cell death*

45
46
47
48
49 As described above, half of the studies show that autophagy is required for the efficient
50
51 killing of tumor cells when treated with anticancer therapies. In line with these observations,
52
53 researchers are working to design new drugs that would induce autophagy by themselves, and
54
55 hence eliminate cancer cells [73]. Among the potential targets in autophagy, the Akt-mTOR
56
57 pathway is the most investigated one. Indeed, proteins Akt, PTEN (Phosphatase and TENsin
58
59
60
61
62
63
64
65

1 homolog) and mTOR, as well as some of the targets of the mTOR kinase, are often
2 overexpressed or mutated in cancer. This pathway regulates numerous survival and
3 proliferation networks in the cell; therefore, its inhibition not only activates autophagy but
4 also cell cycle arrest and/or apoptosis [74]. Specific mTOR inhibitors have been developed
5 and validated, and two of them (Everolimus and Temsirolimus) are now approved for the
6 treatment of renal cell carcinoma and mantle cell lymphoma [75]. Everolimus indeed induces
7 massive autophagy in vivo, with reduced tumoral mass, for example in leukemia [76], in
8 advanced pancreatic tumors [77] and in many other tumors [78]. Concomitant combinations
9 of etoposide, cisplatin or doxorubicin with everolimus produced cooperative antitumor
10 effects, in some cases producing regressions without clinically significant increases in toxicity
11 [79]. One mechanism responsible for this synergy is the activation of p53 by the DNA
12 damaging agent. p53 then transactivates several genes whose products activate autophagy,
13 such as AMPK, ULKs, DAPK1 and TSC2 (Figure 2).

14 Giaccia et al chose another approach, aiming to selectively kill renal clear carcinoma cells,
15 and identified a molecule, STF-62247, that strongly induced autophagy, probably by
16 disturbing protein trafficking between endoplasmic reticulum and Golgi [80]. Blocking
17 autophagy using Atg5 or Atg7 siRNA prevents STF-62247-induced cell death, indicating that
18 autophagy actually functions as a programmed cell death process in these cells.

19 Other drugs have also been shown to enhance autophagy, amongst other effects, all of which
20 might participate in killing cancer cells. They are especially useful in the treatment of
21 apoptosis-resistant cancer cells, for which alternate routes of cell killing must be found [81].

22 As for inducing apoptosis, modulation of some of the Bcl-2 family members also leads to
23 autophagy-dependent cell death. This is notably the case for BH3 mimetics like gossypol that
24 targets Bcl-2, thus allowing Beclin-1 to be released to initiate autophagosome formation [82]
25 (Figure 3). Another example of molecule targeting anti-apoptotic Bcl-2 family members is

Obatoclox, which induces cell death on its own, but also potentiates the effects of other anticancer molecules such as the dual EGFR/HER2 inhibitor lapatinib [83] or HDAC inhibitors [84]. Some of these drugs aimed at elevating autophagy to eradicate cancer cells are currently being tested in clinical trials [73].

4.2 To improve chemotherapeutic treatments

Since high level of autophagy observed in tumor cells following anticancer treatment is thought to represent a protective response, therapeutic targeting of autophagosome formation/fusion might represent a novel molecular avenue to reduce the emergence of chemoresistance [14, 85]. The proof of concept for autophagy inhibition as an adjuvant therapy is demonstrated by the use of chloroquine, a well-known anti-malarial agent, that inhibits lysosomal acidification and blocks the terminal stage of autophagy [86]. Chloroquine has indeed been shown to potentiate the anticancer effects of different drugs both in vitro and in vivo. It is the case for 5-fluorouracil in colon cancer cells [87], in a Myc-induced lymphoma mouse model treated with alkylating agents [88], in mouse models of prostate cancer treated with Src kinase inhibitor [69], or for imatinib-refractory chronic myeloid leukemia cells in combination with the HDAC inhibitor SAHA (suberoylanilide hydroxamic acid) [89]. Current phase I/II clinical trials are underway for evaluating the potential benefit of chloroquine in combination with conventional therapy for a variety of malignancies [73]. Despite the wide use of chloroquine in malaria prevention, some side effects have been reported. They include gastrointestinal problems, stomach ache, itch, headache, nightmares, blurred vision and retinopathy. In overdose, it becomes rapidly toxic. These side effects will have to be addressed if chloroquine is further developed for cancer treatment.

Other molecules display similar effects. 3-methyladenine was shown to enhance cell death induced by 5-fluorouracil in colorectal cancer cell lines [90], cytotoxicity induced by the

1 tyrosine kinase inhibitor imatinib in glioma cell lines [91], as well as in chronic myeloid
2 leukemia cells [89]. Schnekenburger et al have recently shown that the DNA demethylating
3 agent, 2'-deoxy-5-azacytidine, induces autophagy that sensitizes chronic myeloid leukemia
4 cells to conventional treatment [92].
5
6
7
8
9

10 However, it must be remembered that the anticancer effect of these different molecules might
11 not be solely due to their inhibition of autophagy. New studies are needed to develop more
12 specific inhibitors of this process. Targeting ULK1, Beclin-1 or Atg proteins are promising
13 alternative routes.

21 5. Conclusion

22
23
24 The involvement of autophagy in chemotherapeutic agent-induced cell death is very complex.
25 On one hand, autophagy may protect from apoptosis and hence, autophagy inhibitors have
26 potential use as drugs to overcome anticancer therapy resistance. On the other hand, this
27 process participates in cell death in certain circumstances. In that case, its induction may help
28 to eradicate malignant cells. In order to reach clinical application, we must first better
29 understand the factors that influence the effects of autophagy on cell death. Direct crosstalk
30 between apoptosis and autophagy has been evidenced, and some of the mechanisms involved
31 are aimed at reinforcing cell death [93, 94]. A second issue to unravel would be to investigate
32 whether the intensity and/or the speed of the autophagic process would determine the fate of
33 the cell: severe and/or rapid autophagy might lead to cell death while mild and/or slow
34 autophagy may favor cell survival. These different issues are summarized in Figure 4. The
35 role of selectively targeted autophagy is another avenue of research. Indeed, as mentioned
36 previously, hypoxia is known to trigger autophagy that actually thwarts cell death. Previous
37 investigations demonstrated that selective autophagy for mitochondria – mitophagy –
38 prevents accumulation of damaged organelles that are sources of ROS. Determining whether

65

1 this is also true for circumstances other than hypoxia and identifying the molecular
2 mechanisms responsible for orientating autophagy to specific organelles would help to clarify
3
4 the dual role of autophagy in regulating cell death.
5
6

7
8 Finally, the last step of autophagy involves autophagosome fusion with a lysosome. During
9
10 the last decade, it was shown that destabilization of the lysosomal membrane and the partial
11
12 release of lysosomal content into the cytosol can initiate and/or participate in apoptosis
13
14 initiation. Despite being switched on, autophagy final step may be halted in such a situation.
15
16 In this case, the cell has no choice but to die. On the other hand, with intact lysosomes, the
17
18 final outcome could be survival. This hypothesis also needs to be experimentally tested.
19
20
21

22
23 Dysregulated autophagy is a hallmark of cancer cells; the challenge now is to decipher how to
24
25 manipulate it for developing better therapeutic approaches for cancer patients.

11

12
13
14
15
16
17 Figure 2: Schematic representation of the cell death-inducing effects of mTOR inhibitors.
18 mTOR inhibitors such as temsinolimus and everolimus activate autophagy that participates in
19 cell death. This synergizes with the effects of DNA damaging agents via the activation of p53.
20 p53 transcriptionally increases the expression of several proteins known to induce autophagy
21 such as AMPK, ULKs, DAPK-1 and TCS2.
22

28
29
30
31
32

33
34 Figure 3: Schematic representation of the cell death-inducing effects of BH3 mimetics. On
35 one hand, BH3 mimetics releases pro-apoptotic proteins like Bax or Bak from their inhibitory
36 interaction with the anti-apoptotic members of the Bcl-2 family, hence inducing apoptosis
37 through cytochrome c release from the mitochondria and caspase activation. On the other
38 hand, these molecules also liberate Beclin-1 from Bcl-2 localized on the ER. Freed beclin-1
39 then induces autophagy. Both apoptosis and autophagy take part in inducing cell death.
40
41
42
43
44
45
46
47
48
49
50
51

52
53 Figure 4: Schematic representation of the dual action of autophagy in regulating
54 chemotherapeutic agent-induced cell death. On one hand, anticancer molecules induce
55 apoptosis through the intrinsic pathway involving cytochrome c release from the
56 mitochondria and caspase activation. A positive feedback loop involves caspase-dependent
57
58
59
60
61
62
63
64
65

1 cleavage of Beclin-1; truncated Beclin-1 then relocates to mitochondria to enhance
2 cytochrome c release. Apoptosis may also be triggered by the activation of calpain that
3
4 cleaves to Atg5; truncated Atg5 then translocates to the mitochondria and interacts with Bcl-
5
6
7 X_L. Autophagy induction occurs via JNK activation that release Beclin-1 from Bcl-2 by
8
9 phosphorylating the latter. Chemotherapeutic agents also trigger autophagy. Several
10
11 mechanisms are involved. One pathway involves JNK that releases Beclin-1 from its
12
13 inhibitory interaction with Bcl-2 at the level of the ER, via Bcl-2 phosphorylation. Whether
14
15 autophagy is protective or cytotoxic may be due to its severity or duration. Mild and/or slow
16
17 autophagy may enhance cell survival while more severe and/or rapid autophagy would take
18
19 part in inducing to cell death.
