KERNEL DENSITY ESTIMATION
WITH RIPLEY’S CIRCUMFERENTIAL CORRECTION

ARTHUR CHARPENTIER AND EWEN GALLIC

KEYWORDS: border bias; edge correction; frontier; GIS; kernel estimation; polygons; Ripley’s circumference method; spatial process; visualization
Abstract. In this paper, we investigate (and extend) Ripley’s circumference method to correct bias of density estimation of edges (or frontiers) of regions. The idea of the method was theoretical and difficult to implement. We provide a simple technique – based of properties of Gaussian kernels – to efficiently compute weights to correct border bias on frontiers of the region of interest, with an automatic selection of an optimal radius for the method. We illustrate the use of that technique to visualize hot spots of car accidents and campsite locations, as well as location of bike thefts.

1. Introduction and motivation

Visualizing the density of a spatial process is not only a preliminary step in a spatial analysis, but is also useful for reporting results in a simple and understandable way. Flexible techniques to geographically visualize data, and occurrences of a spatial process, are necessary. Kernel smoothing has always been a popular technique to estimate a density. Nevertheless, as mentioned in Bailey (1994), "kernel smoothing over irregular areal units provides difficulties". Edge corrections are necessary to avoid misinterpretations. K-functions, introduced in Ripley (1976), can be used to compute quantities with an edge correction, taking into account boundary configurations of a specific area. But as mentioned in Zheng et al. (2004), “Current algorithms for edge-correction are either difficult to apply or computationally expensive, especially for complex borders”.

This paper addresses this challenge by developing a simple and efficient correction to kernel density estimation, inspired by Ripley’s circumferential method (described in Ripley (1976), Ripley (1977) and Ripley (1981)). In kernel density estimation, we simply count the number of observations in the neighborhood of a given location: the closer an observation, the larger the weight. The shape of the weight function is the kernel, and the length of the neighborhood (also called ‘sphere of influence’ in Hearnshaw et al. (1994)) is the bandwidth parameter. Since Epanechnikov (1969) proved that statistical results were not (significantly) affected by the choice of the kernel function, most of the authors have emphasized the fact that bandwidth’s choice
RIPLEY’S CIRCUMFERENTIAL CORRECTION

is the crucial issue in this problem. The most popular kernel is the Gaussian one since a dual representation (occurrence’s locations observed with a random noise) can be used. Nevertheless, if such kernel estimators are easy to compute, and satisfy good statistical properties, Yamada and Rogerson (2003) recall that this methodology suffers a so called “edge effect” also known in statistical literature as “border bias”. Yamada and Rogerson (2003) mention Ripley’s circumference method (from Ripley (1981)), but claim that “Ripley’s method could be too complicated without proper software or skilled programmers”. In this paper we explain how to use that technique, and provide also a way to select the “optimal” circumferential parameter.

In this paper, basics on space kernel density estimation are recalled in Section 2. Notations and heuristics of kernel density estimation are given in Section 2.1 and 2.2. In Section 2.3, we provide a discussion on the optimal choice of the bandwidth. Then, Section 2.4 provides a discussion on frontiers and space border bias correction. More specifically, Ripley’s circumferential method (from Ripley (1976) and Ripley (1977)) is described in Section 2.5 and again, heuristics on the interpretation of the weights (in the context of kernel estimation) are given in Section 2.6. In Section 3, we discuss the link between the radius $r$ used in the circumferential method, and bandwidth $h$ of the kernel smoother. Using Monte Carlo simulation, given a bandwidth $h$, we show that there is an “optimal” radius $r^*(h)$. Using either a $L_1$ or $L_2$ norm (minimizing either the sum of absolute values of errors or sum of squares of errors) we see that $r^*(h)$ is linear in $h$. This property (analytically derived for half space regions) allows us to introduce an automatic technique. Sections 4 to 6 feature illustrations of this technique, through three examples (see Figure 1 for a quick visualization of the spatial distribution of observations). Section 4 offers an estimation of the density of the location of bodily injury car accidents, in western part of France (Morbihan and Finistère). The impacts of the correction are examined (with respect to standard kernel estimation) and the technique is used to identify hot spots. Section 5 presents an estimation of the density of the location of bike thefts in San Francisco. The interpretation of the density is tackled in that section. An estimation of the density
of the locations of camping spots is presented in Section 6. Finally, Section 7 concludes this article.

![Figure 1. Illustrations: car accident locations (Section 4) in Western part of France Finistère and Morbihan, on top, bike theft locations (Section 5) in San Francisco in the bottom-left panel, and camping spots locations (Section 6) in France in the bottom-right panel.]

2. ON KERNEL DENSITY ESTIMATION

2.1. Interpretation of a spatial density. In the context of a spatial process, with locations $Z_1, \cdots, Z_n$, the interpretation of the value of the density is the following. For any region $\mathcal{E}$,

$$\mathbb{P}(Z \in \mathcal{E}) = \int_{\mathcal{E}} f(z)dz,$$

where $f(z)dz$ is usually interpreted as the probability of $Z$ to fall within the infinitesimal (rectangular) region $[z, z + dz]$, which is the area between $(x, y)$ and $(x + dx, y + dy)$, when $dz$ is small. Here, units of the projection coordinates used to

---

1Codes used in this article to compute $\hat{f}$ and visualize it on a map is described (and fully available) on https://github.com/ripleyCorr/Kernel_density_ripley.
locate \( z \) are \( 1^\circ \) (111.11 km) times \( 1^\circ \) (111.11 km on the Equator, but 87.8 km in San Francisco for instance, and more generally 111.11 times \( \cos(y) \)). In the San Francisco area (discussed in Section 5) the unit corresponds to a 9,758 \( km^2 \) area, for instance.

It is possible to relate the density \( f(z) \) to the expected number of observations that should occur in a neighborhood of \( z \). At location \( z = (x, y) \), the expected number of observations within a distance \( r \) of location \( z \) (in km) is

\[
\frac{n \times f(z) \times \pi r^2}{111.11^2 \times \cos(y)}.
\]

In the context of San Francisco, a density \( f(z) = 100 \) means that about \( n/250 \) observations should be within a 500 \( m \) distance of \( z \). Hence, the density \( f(z) \) can easily be related to the expected number of observations of the spatial process within a given distance to \( z \). See Section 5.2 for a longer discussion on the interpretation of the density.

2.2. Definitions and notations. Kernel density estimation (see Scott (2009), Silverman (1986), Wand and Jones (1994)) is a standard statistical technique to estimate a smooth probability density function. It has been extended from univariate distributions (on the real line) to multivariate distributions, including spatial and spatio-temporal models. Spatial observations are based on spatial locations \( Z_i = (X_i, Y_i) \) (usually characterized by a latitude and a longitude). Based on a sample \( \{Z_1, \cdots, Z_n\} \) the estimation of the density at point \( z = (x, y) \) is

\[
\hat{f}_H(z) = \frac{1}{n} \det(H)^{-1} \sum_{i=1}^{n} K\left( H^{-1}(z - Z_i) \right),
\]

(2.1)

where \( K \) is some symmetric (centered) kernel function, and \( H \) a bandwidth parameter. A popular kernel is the quadratic one, introduced by Epanechnikov (1969), used \( e.g. \) in ArcGIS, and defined as

\[
K(u, v) = \frac{2}{\pi} (1 - [u^2 + v^2]) \mathbf{1}(u^2 + v^2 \in [0, 1)).
\]

(2.2)
An alternative is to consider Gaussian kernels, \(i.e.\) \(K_Z\) is the density of a Gaussian random vector,

\[
K(u, v) = \frac{1}{2\pi\sqrt{1-\rho^2}} \exp\left(-\frac{1}{2(1-\rho^2)} [u^2 + v^2 - 2\rho uv]\right).
\]  

(2.3)

For convenience, it is rather common to consider a kernel with independent components, and a diagonal bandwidth parameter, where values are identical if the spatial process is homogeneous in both directions:

\[
\hat{f}_h(z = (x, y)) = \frac{1}{nh^2} \sum_{i=1}^{n} K\left( \frac{x - X_i}{h} \right) \cdot K\left( \frac{y - Y_i}{h} \right).
\]  

(2.4)

2.3. On optimal bandwidth. In the context of product of (symmetric) kernels, one can prove using Taylor’s expansion, that

\[
\mathbb{E}[\hat{f}_h(z)] \sim f(z) + \alpha_1 \left( \frac{h_x^2}{2} \frac{\partial^2 f}{\partial x^2} f(z) + \frac{h_y^2}{2} \frac{\partial^2 f}{\partial y^2} f(z) \right) \quad \text{and} \quad \text{Var}[\hat{f}_h(z)] \sim \frac{\alpha_2}{nh_xh_y} f(z)^2,
\]

where \(\alpha_2\) and \(\alpha_2\) are parameters related to the shape of the kernel function, see Wand and Jones (1994) and Scott (2009) for more details on the exact value of those parameters. The mean integrated squared error is then

\[
\text{MISE}(h) = \mathbb{E} \left[ \int [\hat{f}_h(z) - f(z)]^2 dz \right] \sim \alpha_3 h^4 + \frac{\alpha_4}{nh},
\]

so \(h^* = \text{argmin}\{\text{MISE}(h)\}\) is \(\alpha n^{-1/5}\) for some constant \(\alpha\) (function of the kernel as well as the true – unknown – density \(f\)). In the case where the true density \(f\) is a Gaussian distribution, with a diagonal variance matrix \(\Sigma\), Silverman’s rule of thumb can be used (see Silverman (1986) and Scott (2009) for a discussion)

\[
h_i^* \sim \left(\frac{2}{3}\right)^{\frac{1}{6}} \cdot \sigma_i \cdot n^{-1/6}.
\]

2.4. Frontier and space border bias. Kernel density estimation is a popular technique to visualize unbounded smoothed densities. But in some specific cases, observations have to lie within some specific area \(S\). For instance, for traffic accidents or bike thefts, events have to occur on-land, as discussed in Sections 4 and 5, respectively. \(S\) would stand for some on-land territory. On the contrary, when locating fishes or sea
animals using GPS trackers, it is known that those animals have to be in the sea. In that case, $S$ would represent some territorial sea.

In the case where $S$ is bounded, kernel estimates (with symmetric kernels) suffer two important drawbacks:

- the total weight is not equal to 1, leading to an incorrect probability distribution function\(^2\), \(i.e. \int_S \hat{f}(z)dz < 1\),
- close to the frontier $\partial S$, $\hat{f}$ has a multiplicative bias, \(i.e. E[\hat{f}(z)] = \kappa_z \cdot f(z)\), where $\kappa_z \in [0, 1]$ depends on the shape of the border $\partial S$ in the neighborhood of $z$.

As shown in Section 3, in the context of on-land events for regions closed to the sea, estimators of density can behave very defectively. The idea here is to propose a methodology which gives an estimator $\hat{f}$ which could be associated to a proper probability distribution function, and which does not suffer border bias.

### 2.5. Ripley’s circumferential correction

The (univariate) kernel density estimator for a uniform kernel – also called ‘moving histogram’ – is defined as

$$\hat{f}_h(x) = \frac{1}{nh} \sum_{i=1}^{n} 1(d(x, X_i) \leq h), \text{ where } d(x, X_i) = |x - X_i|.$$ 

It simply consists in counting the number of observations within a distance $h$ of the arbitrary point $x$. In the context of a two-dimensional spatial density, Ripley (1976) extended the notion above by implementing the $K$ function, where only observations within a distance $h$ of an arbitrary point $(x, y)$ were considered:

$$\hat{f}_h(z) = \frac{1}{nh} \sum_{i=1}^{n} 1(d(z, Z_i) \leq h), \text{ where } d^2(z, Z_i) = (x - X_i)^2 + (y - Y_i)^2.$$ 

\(^2\)In standard statistical packages, the estimations are usually normalized so that the overall mass (on the area where the density is computed) is equal to 1. A multiplicative coefficient is applied uniformly on the whole area, while a local adjustment is, obviously, necessary: the density is still underestimated on the edge $\partial S$. 
Ripley (1977) suggested a "proper edge correction method", that we can write – using our own notations for consistency

\[ \hat{f}_h(z) = \frac{1}{nh} \sum_{i=1}^{n} \frac{1}{\omega_i(z)} \mathbf{1}(d(z, Z_i) \leq h), \]

where the weight, \( \omega(z) \) is defined as the proportion of a circumference of a circle centered at point \( z \) that lies within the study area \( S \). As claimed in Yamada and Rogerson (2003) "although it is difficult to derive \( \omega \)'s analytically for an arbitrarily shaped study area, it would still be possible to derive it numerically using GIS". This method is called Ripley’s circumference method in Cressie (1992) and Bailey and Gatrell (1995).

2.6. Interpretation of the weight based correction. Recall that kernel estimators of densities can be seen as the expected value of the density for sample \( \{ \tilde{Z}_i = Z_i + \epsilon_i \} \) where \( \epsilon_i \)'s are i.i.d. random noises, independent of the observations, as in Davis (1975), Tapia and Thompson (1978) or Stefanski and Carroll (1990). Further, the empirical cumulative distribution function is the step function defined as

\[ \hat{F}(z) = \frac{1}{n} \sum_{i=1}^{n} \mathbf{1}(Z_i \leq z), \]

and the associated empirical measure is

\[ \hat{f}(z) = \frac{1}{n} \sum_{i=1}^{n} \delta_{Z_i}(z), \]

where \( \delta \) denotes the Dirac measure. The idea of Kernel based estimator is to substitute a continuous distribution to Dirac measures,

\[ \hat{f}(z) = \frac{1}{n} \sum_{i=1}^{n} \mu_{Z_i}(z), \]

where \( \mu_{Z_i} \) can be the density of a Gaussian vector, centered in \( Z_i \), with variance-covariance matrix \( H \). The problem is that if the distribution of \( Z \) has a bounded support, then measure \( \mu_{Z_i} \) will spread some weight in areas where no observation can
be found (outside $\mathcal{S}$). Thus, it might be natural to consider a truncated distribution, restricted to the support $\mathcal{S}$:

$$
\mu_{\mathbf{Z}_i|\mathcal{S}}(z) = \frac{\mu_{\mathbf{Z}_i}(z)}{\mu_{\mathbf{Z}_i}(\mathcal{S})}.
$$

Thus, it is natural to consider

$$
\hat{f}(z) = \frac{1}{n} \sum_{i=1}^{n} \mu_{\mathbf{Z}_i|\mathcal{S}}(z) = \frac{1}{n} \sum_{i=1}^{n} \omega_i \cdot \mu_{\mathbf{Z}_i}(z) \text{ where } \omega_i = \mu_{\mathbf{Z}_i}(\mathcal{S})^{-1}.
$$

(2.9)

If we consider a noise with circularly contoured distribution (e.g. a Gaussian noise, as mentioned earlier), it is possible to approximate $\mu_{\mathbf{Z}_i}(\mathcal{S})$ by

$$
\mathcal{A}(\mathcal{D}_{\mathbf{Z}_i,r} \cap \mathcal{S}) / \mathcal{A}(\mathcal{D}_{\mathbf{Z}_i,r}),
$$

(2.10)

where $\mathcal{A}$ denotes the area function, and $\mathcal{D}_{\mathbf{Z}_i,r}$ the disk centered in $\mathbf{Z}_i$ with radius $r > 0$. This weight is the same as the one used in Ripley’s circumference method (from Ripley (1976)). Note that $r$ should be related to the covariance matrix $\mathbf{H}$ (this will be discussed in section 3), since the later is related to the width of the neighborhood: the wider the neighborhood, the larger the radius. Thus, here, the idea is simply to use weighted kernel estimators:

$$
\hat{f}(z) = \frac{1}{n} \sum_{i=1}^{n} \omega(\mathbf{Z}_i) \cdot \det(\mathbf{H})^{-1} K\left(\mathbf{H}^{-1}(\mathbf{z} - \mathbf{Z}_i)\right),
$$

(2.11)

where weights $\omega(\mathbf{Z}_i)$ should reflect the proportion of area around $\mathbf{Z}_i$ (within distance $r$) that belongs to $\mathcal{S}$. Those weighted kernel estimators have been intensively used, e.g. on censored data, as in Marron and Padgett (1987) (to correct censoring bias) or Gisbert (2003). As mentioned in Hall and Turlach (1999), having weights that depend only on the data ($\mathbf{Z}_i$’s) and not on the location ($\mathbf{z}$) is interesting from a computational point of view. From this assumption, and since computing intersection of polygon areas with standard softwares is extremely simple, Ripley’s circumferential technique can easily be implemented.

**Example 1.** The use of weights is illustrated on Figure 2 in the univariate case: on border, the kernel is no longer the density of a Gaussian distribution centered on $X_i,$
but the density of a truncated Gaussian distribution. Thus, those weights have an impact on the border of the support.

Figure 2. Weight correction of a density on [0, 1]: kernel $K$ is no longer a Gaussian density, but a truncated Gaussian density.

Example 2. The use of weights is illustrated on the top-left graph of Figure 3 on a non-convex polygon $S$. The weights are the proportion of the disk that lie in the polygon. On the top-left graph of Figure 3 some specific locations are mentioned (they will be used later on, for an intensive simulation study). Points will be uniformly drawn within the region $S$. The theoretical density can be visualized below, with the three dimensional surface on the bottom-left graph and iso-density curves on the bottom-right graph of Figure 3. An estimation based on 500 simulated observations (uniformly drawn on $S$) can be visualized on Figure 4. Top graphs are the estimation of the density $f$ using a Gaussian kernel technique. Border bias can clearly be observed. Bottom graphs are the estimation of the density $f$ using a Gaussian kernel technique with Ripley’s correction. The estimator is volatile (mainly because of the small sample size), but it seems much better than the previous one.
3. Optimal radius $r$ for the circumferential correction

With a Gaussian kernel, in the univariate case, the bandwidth $h$ is the standard deviation of the Gaussian noise $\varepsilon$ (see Chiu (1991)), and in the bivariate case, $H$ is the covariance matrix of the noise, $\varepsilon$. Then the true probability $\mu_{Z_i}(S)$ is

$$\mathbb{P}(Z_i + \varepsilon \in S) \text{ where } \varepsilon \sim \mathcal{N}(0, H). \quad (3.1)$$

3.1. Kernel product with identical bandwidth. A standard assumption in multivariate density estimation is to assume that $K$ is the product of two (univariate)
kernels. This assumption can be interpreted as a non-correlated noise $\varepsilon$, i.e. $H$ is a diagonal matrix. From the geography of our problem, it is possible to assume further that the two components have the same 'dimension', thus, it might not be a too strong assumption to assume that $H$ is a diagonal matrix with identical terms on the diagonal. Let $h$ denote this diagonal term (this assumption will be relaxed at the end of this section), so that level curves of the density of $Z$ are circles.
3.1.1. **Analytical computation when \( S \) is a half-plane.** If \( S \) is a half-plane, and if the distance between \( Z_i \) and the border is \( \alpha \), then

\[
P(Z_i + \varepsilon \in S) = 1 - \Phi(-\alpha h^{-1}) = \Phi(\alpha h^{-1}),
\]

where \( \Phi \) denotes the cumulative distribution function of the \( \mathcal{N}(0,1) \) distribution (see Figure 5).

![Figure 5. Link between \( P(Z_i + \varepsilon \in S) \) and \( A(D_{Z_i,r} \cap S) \) where \( S \) is a half-plane.](image)

Assume for convenience that \( h = 1 \), and that \( a = 1 \), then the probability that \( Z_i + \varepsilon \notin S \) is \( \Phi(-1) \sim 15\% \). The proxy we suggest for \( \mu_{Z_i}(S) \) is to consider the following ratio:

\[
\mu^\circ_{Z_i}(r; S) = \frac{A(D_{Z_i,r} \cap S)}{A(D_{Z_i,r})},
\]

where \( D_{Z_i,r} \) is a disk centered in \( Z_i \) with radius \( r \). Again, if \( S \) is a half-plane, it is possible to derive an analytical expression, since it will just be related to the *circular segment* (the region bounded by a chord and the arc subtended by the chord, see...
Figure 5). The area of the circular segment is equal to the area of the circular sector minus the area of the triangular portion:

$$A(D_{Z_i, r} \cap S) = \frac{\theta}{2} \pi r^2 - \frac{r^2 \sin(\theta)}{2} \text{ where } \cos \left( \frac{\theta}{2} \right) = \frac{a}{r}. \quad (3.4)$$

Thus,

$$A(D_{Z_i, r} \cap S) = \begin{cases} \frac{r^2}{2} [\theta - \sin(\theta)] & \text{if } a < r \\ 0 & \text{if } a > r \end{cases}. \quad (3.5)$$

From the previous computation, we would like to find $r^*$ (or $\theta^*$) such that $A(D_{Z_i, r} \cap S)$ is 15% of $A(D_{Z_i, r})$, when $a$ is equal to 1, i.e.

$$\frac{r^2}{2\pi r^2} [\theta - \sin(\theta)] = \frac{1}{2\pi} [\theta - \sin(\theta)] = 15\% \ (= \Phi(-1)), \quad (3.6)$$

or equivalently,

$$\theta^* - \sin(\theta^*) = 2\pi \Phi(-1) \sim 1,$$

thus, $\theta^* = 1 + u$ where $u$ is the root of $\sin(1 + u) = u$, which is numerically equal to 0.93. Since $\theta = 2 \arccos(r^{-1})$, then $r^* \sim 1/\cos(1.93/2)$ which is numerically equal to 1.76. Therefore, with a disk with radius 1.76, the area of the circular segment located at 1 from the center of the disk is 15% of the area of the disk.

More generally (with any $a$ and $h$), if $r^* = \beta^* h$, the ratio of the area of the circular segment is

$$\frac{\theta^* - \sin(\theta^*)}{2\pi} = \frac{1}{2\pi} \left[ 2\arccos \left( \frac{a}{\beta^* h} \right) - \sin \left( 2\arccos \left( \frac{a}{\beta^* h} \right) \right) \right]. \quad (3.7)$$

Let $x = ah^{-1}$ and $b = 1/\beta^*$, then the ratio is

$$x \mapsto \frac{1}{2\pi} [2\arccos (bx) - \sin (2\arccos (bx))]. \quad (3.8)$$

Taylor’s expansion (when $x$ is closed to 0) is

$$x \mapsto \frac{1}{2} - \frac{2b}{\pi} x + \frac{b^2}{3\pi} x^3 + \frac{b^5}{20\pi} x^5 + O(x^7).$$

Following Shah (1985) and Bryc (2002), Taylor’s expansion of $\Phi(-x)$ is

$$\Phi(-x) \sim \frac{1}{2} - 0.368929 x - 0.037758 x^3 + O(x^5).$$
Therefore, linear terms are equal when $\beta^* = 2/(0.3689\pi) \sim 1.725$. The use of a linear relationship, with a proportionality factor around 1.76 seems to be legitimate.

The intuition is that $r^*$ might be a (linear) function of $h$, $r^* = \beta^* h$ where $\beta^* \sim 1.76$, with half-plane domains. And this relationship might also be a good approximation on more general spaces $S$.

3.1.2. Monte Carlo study for more complex areas $S$. In order to illustrate the general case, two regions are considered in this section: the polygon of Figure 3, and the contour of Finistère (the French region). In those two regions, 10,000 points are drawn uniformly $Z_i$ (1,000 are plotted on Figure 6).

![Figure 6](image_url)

**Figure 6.** Polygon $S$ on the left and the Finistère region on the right, where 1,000 points are uniformly drawn.

Given $h > 0$,

- theoretical weights $\omega_i(h)$ are numerically computed, based on $\mu_{Z_i}(S) = \mathbb{P}(Z_i + \varepsilon \in S)$, using Monte Carlo simulations, since $\varepsilon \sim \mathcal{N}(0, h\mathbb{I})$,
- $\omega_{i}^{\circ} (h)$ are computed, based on $\mu_{r_iZ_i}(S)$ for different values of $r$,
- for some norm $\| \cdot \|$, the optimal radius $r^*$ is solution of

$$r^*(h) = \arg\min \left\{ \sum_{i=1}^{n} \| \omega_{i}^{\circ}(h) - \omega_{i}(h) \| \right\},$$

(two norms are considered in this study $\| x \|_1 = |x|$ and $\| x \|_2 = x^2$).

On Figure 7, $h \mapsto r^*(h)$ is plotted on top, where a linear relationship can easily be identified, and below the slope, *i.e.* $h \mapsto r^*(h)/h$. The horizontal dashed line is the
1.76 value obtained empirically in the computations of the previous section (using a half-plane region).

Thus, from bandwidth $h$, it is possible to approximate weights using

$$\omega_i(h) = \frac{\mathcal{A}(D_{Z_i, r^*})}{\mathcal{A}(D_{Z_i, r^*} \cap S)}$$

where $r^* = \beta^* h$ and $\beta^* \sim 1.76$.

3.2. Comparison with other corrections. A method for edge correction of an intensity estimator was introduced in Diggle (1985), including a discussion on the
bandwidth estimation (see also Berman and Diggle (1989) and the estimation of relative risk (see Kelsall and Diggle (1995)). In Section 2.3, we explained how to estimate densities at various points \( z \)’s, and we mentioned that a standard global measure to assess the quality of the fit was to use the mean integrate squared error (where the mean squared error is integrated on the whole area) with

\[
\text{MSE}(z, h) = \mathbb{E} \left[ \left( \hat{f}_{h}(z) - f(z) \right)^2 \right] = \mathbb{E} \left[ \left( \hat{f}_{h}(z) - f(z) \right)^2 \right] + \text{Var} \left[ \hat{f}_{h}(z) \right].
\]

Here we estimate that function using simulations, and the two components (bias and variance) are reported on Figure 8. \( n_s = 1,000 \) samples of \( n \) points uniformly drawn on the polygon of Figure 3 are generated. The density is displayed on the diagonal of the upper-left corner \( [B, D] \) (as defined on Figure 3). For any point \( z \), estimators \( \hat{f}_1(z), \cdots, \hat{f}_{n_s}(z) \) (with the two techniques) are obtained, based on those \( n_s = 1,000 \) samples. The average value of those estimators, \( \bar{f}(z) \) (which is a approximation of \( \mathbb{E}[\hat{f}_{h}(z)] \)), as well as the variance,

\[
\text{Var}[\hat{f}(z)] = \frac{1}{n_s - 1} \sum_{i=1}^{n_s} \left( \hat{f}_i(z) - \bar{f}(z) \right)^2 \text{ with } \bar{f}(z) = \frac{1}{n_s} \sum_{i=1}^{n_s} \hat{f}_i(z),
\]

(which is an approximation of \( \text{Var}[\hat{f}_{h}(z)] \)) are plotted on Figure 8, for all \( z \in [B, D] \).

Figure 8, shows that both estimators have a similar behavior on average, but the variance (and therefore the mean-squared error) is much smaller with Ripley’s correction, especially on small samples. Besides, Figure 9 exhibits much more volatility for Diggle’s correction (on the right) compared to our estimate (with Ripley’s correction, on the left).

4. Visualizing locations of car accidents

Car accident concentration is usually identified as black spots, as in Nguyen (1991) or Joly (1992). Those zones suggest that there might exist some spatial dependence between individual occurrences, as suggested by Steenberghen et al. (2004). Detecting clustering (in time and space) might be an important issue, to improve road safety and to reduce traffic accidents. We consider here the dataset of traffic accident, that
Figure 8. Estimation of the density in the upper left corner of polygon $S$, on interval $[B, D]$, with $n = 100$ and $n = 1,000$ points, on the left and on the right, respectively, with the average density (on 1,000 samples), and the standard deviation.

occurred in 2008 in France and involved bodily injuries. The BAAC dataset (bulletins d’analyse d’accident corporel) is filed by police forces, and most accidents have a specific location. In 2008, the dataset contains 10,854 accidents with a location.
Figure 9. Estimation of the density in the upper left corner of polygon $S$, on interval $[B, D]$, with $n = 100$ and $n = 1,000$ points, on the left and on the right, respectively, with the average density (on 500 samples), and the standard deviation.

4.1. **Spatial location of bodily injury car accidents in two regions.** In order to illustrate border issues, we focus here on two specific regions, Finistère and Morbihan\textsuperscript{3},

\textsuperscript{3}Note that islands were removed, namely Belle-Ile, Ile de Groix, Ile de Hoëdic and Ile d’Houat since no traffic accident occurred on those islands in 2008.
where major cities (Brest in Finistère and Lorient, or Vannes in Morbihan are next to the sea). There are 186 observations for the first region, and 180 for the other one.

Results of the estimations for Finistère can be seen on Figure 10. When the standard kernel is used, we can think of at least two black spots, with one in the North being more important than the other one in the South coastline. When the correction is used, the two spots still show up, but another locale stands out on the lower tip of Finistère. The area of this third place is surrounded by water, thus the estimation with standard kernel fails to highlight it.

The same happens in Morbihan, as seen on Figure 11. The density estimation at the North-West frontier is really different depending on the use of weight corrections. Once weights are applied to correct the border bias, one can easily detect a black spot.

![Figure 10](image1.png)

**Figure 10.** Locations of car accidents, in Finistère, standard kernel on the left, and corrected one on the right.

4.2. Detecting hot spots. In order to improve road safety and to reduce traffic accidents, public authorities have to understand where traffic accident occurred. Analysis of spatial patterns is then a crucial issue, since it is difficult to assume that occurrences of traffic accidents are purely random observations, in space. In most cases, traffic accidents form clusters, called “hot spots”, in geographic space (see Taylor (1977) or Steenberghen et al. (2004)). Spatial (and temporal) patterns along a certain roadway segment are largely determined by their traffic volume, but also physical environment (slopes and angles) or weather (see Black (1991), Noland and Quddus (2004) and
Detecting spatial patterns and clusters of car accidents is a recurrent problem (see Yamada and Thill (2004), Erdogan et al. (2008), Xie and Yan (2008), Loo (2006) and reference therein). The so-called “quadrat” analysis (see Getis (1964), Rogers (1965) or Thomas (1977) for a description) is one popular technique to analyse the pattern of a distribution of events within a given region $S$. The idea is to divide region $S$ into sub-regions $S_i$’s having equal (and homogeneous) areas, called quadrats and to study histograms on this partition of $S$. GIS packages allow then visualizing the phenomenon via color-based representations of quadrats. Nevertheless, the analysis is then extremely sensitive to the partition considered.

As described in Chapters 7 of Levine (2010) (see also Levine (2008) for additional motivations and Everitt et al. (2011) for more technical discussions), it is possible to use the density estimation to identify and visualize hot spots. In Levine (2010), a “Single Kernel Density method” is considered. It is employed here on the accidents data, and referred to as “the estimate without border correction”. Ripley’s correction is also applied to visualize hot posts. Figure 12 displays the convex hull of the hot-spot regions for car accidents, for both estimation techniques.

Further, following Chainey et al. (2002) and Van Patten et al. (2009), the Predictive Accuracy Index (PAI) can be computed, as the ratio of the hit rate percentage in the hot spot to the area percentage (area in the hotspot in relation to the study’s total area). PAI’s using Ripley’s correction are reported in the last column of Table 1.
5. Vizualizing bike theft locations

5.1. Density estimation of bike theft locations. Another popular area of applications, where visualizing spatial densities is also a crucial step, is criminology (see Block et al. (1995), Eck (1997), Ceccato and Haining (2004), Levine (2010) or Nakaya and Yano (2010) among others). In order to illustrate Ripley’s correction technique, another application on bike thefts in San Francisco is considered. Data about reported crimes in San Francisco are available on https://data.sfgov.org/. Density estimates are computed as a first step, on the 794 reported bicycle thefts from 2013. These estimates are used in a second step to compute an estimation of the number of stolen bikes per year within a 500 m radius.

5.2. On the interpretation of the density. As discussed in Section 2.1, for any region $\mathcal{E}$,

$$P(Z \in \mathcal{E}) = \int_{\mathcal{E}} f(z) dz,$$
Figure 13. Estimates of expected bike thefts per year within a 500 m radius on the left, and corrected kernel density estimates on the right (zoom).

where \( f(z)dz \) is usually interpreted as the probability of \( Z \) to fall within the infinitesimal region \([z, z + dz]\). Here, units of the projection coordinates used to locate \( z \) are 1° (111.11 km) times 1° (111.11 km on the Equator but 87.8 km in San Francisco), which is a 9758 km² area. Therefore, the whole area \( S \) of San Francisco (120.11 km²) is 1/81 of the total 1° times 1° area: a uniform distribution over San Francisco would be \( f_{\perp}(z) \sim 81 \).

To have an interpretation of the density in terms of the number of bikes stolen per year within a given area \( D \) – say a 500 m distance to location \( z \) – then \( \mathbb{P}(Z \in D) \sim f(z)A(D \cap S) \), where \( D \) is the disk of radius \( r \) centered in \( z \). If the distance from \( z \) to the sea exceeds \( r \), then \( \mathbb{P}(Z \in D) \sim f(z) \cdot A(D) \). A circle of radius 500 m is 0.785 km²; and since the whole area \( S \) of San Francisco is 120.11 km², \( A(D) \) is 1/153 of the total San Francisco area. If the distance from \( z \) to the sea is below \( r \), there is a multiplicative factor \( A(D \cap S)/A(D) \) (proportion of the disk inland). This ratio is the same as the one when computing weights for the correction.

Figure 14 shows those computations.

Observe that the interpretation of the number of stolen bikes can be related to the standard kernel density estimation, without the correction. The correction is necessary when computing a density (which can be related to a probability of occurrence
Figure 14. Density estimation $\hat{f}(z)$ - in the middle - at latitude $37.788^\circ$, and estimation of the expected number of bikes stolen, per year, within a 500 m distance to location $z$ - bottom graph. On top, observations in the neighborhood of the latitude can be visualized. A $\pm 500$ m tube was added.

with respect to some unit) but not when computing the number of events that should occur within a given time frame.

6. Vizualizing the density of campsites

The third and last example to apply Ripley’s circumference method concerns campsites locations in France. More generally, from an economic perspective, getting a better geographical perception of the location of accommodation facilities is extremely important, as explained in Hsueh and Tseng (2013). In this example, we will discuss locations of campgrounds, in France. Data about French lodgings were
downloaded at https://www.classement.atout-france.fr, and only observation concerning campgrounds were kept. A total of 5,494 camping pitches were geolocated using the Google Maps API\(^4\). The density estimates can be visualized on Figure 17, with and without applying the correction. Figures 17 and 19 provide zooms on two regions where an abundance of campgrounds can be found near the coastline. In order to highlight the difference, using the technique described in Section 4, convex hull of hot spot areas are also plotted (see Figure 16 for France, 18 for the Mediterranean side, and 20 for the Atlantic side).

\[\text{Figure 15. Density estimates of French campground locations, standard kernel on the left, and corrected one on the right.}\]

\[\text{Figure 16. Convex hull of hot spot areas, without border correction (on the left) and with Ripley’s correction (on the right).}\]

\(^4\text{See https://developers.google.com/maps/}.\)

Figure 18. Convex hull of hot spot areas (zoom on Southern France), without border correction (on the left) and with Ripley’s correction (on the right).

7. Conclusion

In this article, a technique relating kernel density estimation and Ripley’s cirumferential technique was discussed, including a practical technique to select the optimal radius of Ripley’s correction technique. This correction is necessary to provide an adequate visualization of the density. Nevertheless, when interpreting the density as an expected number of occurrences, this correction might be misleading. Computations are fast, and our estimate provided a less volatile estimation of the density, compared to the popular estimate introduced by Diggle (1985). That estimate was used on

three different applications, when regions have different shapes, and with different sample size too.
