ABSTRACT. We study in this paper the behavior of several PRF models, and display their main characteristics. This will lead us to introduce a new heuristic constraint for PRF models, referred to as the Document Frequency (DF) constraint. We then analyze, from a theoretical point of view, state-of-the-art PRF models according to their relation with this constraint. This analysis reveals that the standard mixture model for PRF in the language modeling family does not satisfy the DF constraint. We then conduct a series of experiments in order to see whether the DF constraint is valid or not. To do so, we performed tests with an oracle and a simple family of tf-idf functions based on a parameter k controlling the convexity/concavity of the function. Both the oracle and the results obtained with this family of functions validate the DF constraint.

KEYWORDS: IR theoretical models, pseudo-relevance feedback
1. Introduction

In the language modelling approach to IR, the mixture model for pseudo-relevance feedback is a state of the art algorithm. Numerous studies use it as a baseline, and it has been shown to be one of the most effective models in terms of performance and stability wrt parameter values in (Lv et al., 2009). However, several recently proposed models outperform this model, as models based on bagging, models based on a mixture of EDCM distributions and information models (Collins-Thompson et al., 2007, Xu et al., 2008, Clinchant et al., 2010). We try here to highlight what these new models have in common. This leads us to formulate a heuristic constraint for pseudo-relevance feedback, which we will refer to as the Document Frequency constraint. Our analysis shows that most proposed models meet this heuristic constraint. Finally, we run experiments to assess the validity of this constraint. The notations we use throughout the paper are summarized in table 1, where \( w \) represents a term. We note \( n \) the number of pseudo relevant document used, \( F \) the feedback set and \( tc \) the number of term for pseudo relevance feedback. An important change of notations concerns \( TF \) and \( DF \) which are in this paper related to the feedback set \( F \).

2. Pseudo-Relevance Feedback Statistics

We begin this paper by analyzing the terms chosen and the performance obtained by three different, state-of-the-art, pseudo-relevance feedback (PRF hereafter) methods, namely the mixture model and the divergence minimization method in the language modeling family (Zhai et al., 2001), and the mean log-logistic information model in the information-based family (Clinchant et al., 2010). These models are reviewed later in section 4, and their exact formulation is not necessary here. In order to have

an unbiased comparison, we use the same IR engine for the retrieval step. Thus, all PRF algorithms are computed on the same set of documents. Once new queries are constructed, we use either the Dirichlet language model (for the new queries obtained with the mixture model and the divergence minimization method) or the log-logistic model (for the new queries obtained with the mean log-logistic information model) for the second retrieval step, thus allowing one to compare the performance obtained by different methods on the same initial set of PRF documents. Two collections are used throughout this study: the ROBUST collection, with 250 queries, and the TREC 1&2 collection, with topics 51 to 200. Only query titles were used, which is a common setting when studying PRF (Dillon et al., 2010). All documents were preprocessed with standard Porter stemming.

2.1. Term Statistics

We first focus on a direct comparison between the mixture model and the mean log-logistic information model, by comparing the terms common to both feedback methods, i.e. the terms in the intersection of the two selected sets. Table 2 displays the mean, median and standard deviation of the size of the intersection, over all queries, for the collections considered. As one can note, the two methods agree on a little more than half of the terms (ratio mean by tc), showing that the two models select different terms. To have a closer look at the terms selected by both methods, we first compute, for each query, the total frequency of a word in the feedback set (i.e. TF(ω)) and the document frequency of this word in the feedback set (i.e. DF(ω)). Then, for each query we can compute the mean frequency of the selected terms in the feedback set as well as its mean document frequency, i.e. $q(TF)$ and $q(DF)$:

$$q(TF) = \frac{\sum_{i=1}^{tc} TF(ω_i)}{tc} \quad \text{and} \quad q(DF) = \frac{\sum_{i=1}^{tc} DF(ω_i)}{tc}$$

We then compute the mean of the quantities over all queries.

$$\mu(TF) = \sum_{q} \frac{q(TF)}{|Q|} \quad \text{and} \quad \mu(DF) = \sum_{q} \frac{q(DF)}{|Q|}$$

An average IDF can be computed in exactly the same way. Table 3 displays the above statistics for the three feedback methods: mixture model (MIX), mean log-logistic(LL) information model and divergence minimization model (DIV). Regarding
the mixture and log-logistic models, on all collections, the mixture model chooses in average words that have a higher TF, and a smaller DF. The mixture model also chooses words that are more frequent in the collection since the mean IDF values are smaller. On the other hand, the statistics of the divergence model shows that this model extracts very common terms, with low IDF and high DF, which, as we will see later, is one of the main drawback of this model.

2.2. Performance Statistics

In addition to the term statistics, the performance of each PRF algorithm can also be assessed. To do so, we first examine the performance of the feedback terms without mixing them with the original queries- we call this setting raw. Then, for each query we keep only terms that belong to the intersection of the mixture (respectively the divergence minimization) and log-logistic models, but keep their weight predicted by each feedback method. We call this setting interse. A third setting, diff, consists in keeping terms which do not belong to the intersection. Finally, the last setting, interp for interpolation, measures the performance when new terms are mixed with the original query. This corresponds to the standard setting of pseudo-relevance feedback. Table 4 displays the results obtained. As one can note, the log-logistic model performs better than the mixture model, as found in (Clinchant et al., 2010). What our analysis reveals is that it does so because it chooses better feedback terms, as shown by the performance of the diff setting. For the terms in the intersection, method interse, the weights assigned by the log-logistic model seem more appropriate than the weights assigned by the other feedback models.

Let’s summarize our finding here. (a) The log-logistic model performs better than the mixture and divergence models for PRF. (b) The mixture and divergence models
choose terms with a higher \( TF \) and a smaller \( DF \) than the log-logistic one. A first explanation of the better behavior of the log-logistic model can be that the IDF effect is dealt with more efficiently in this model, as shown by the statistics reported in table 3. We also postulate that the log-logistic model tends to favor terms with a high \( DF \), while the other models favor terms with a low \( DF \). This leads us now to propose a new heuristic constraint for pseudo-relevance feedback.

### 3. Heuristic Constraints

Axiomatic methods were pioneered by Fang et al. (Fang et al., 2004) and followed by many works including (Fang et al., 2006, Cummins et al., 2007, Clinchant et al., 2010). In a nutshell, axiomatic methods describe IR functions by properties. According to (Clinchant et al., 2010), the four main conditions for an IR function to be valid are: the weighting function should (a) be increasing and (b) be concave wrt document term frequencies, (c) have an IDF effect and (d) penalize long documents. In the context of pseudo-relevance feedback, Lv (Lv et al., 2009) mentions a document score heuristic constraint implemented in relevance models (Lavrenko et al., 2001) and in the Rocchio algorithm (Hoashi et al., 2001). The document score heuristic constraint can be formulated as follows:

PRF Heuristic Constraint 1. [Document Score] Document with higher score should be given more weight in the feedback weight function.

Another heuristic is related to the term proximity constraint, that is feedback terms should be close to query terms in documents (Lv et al., 2010).

The development made in the previous section however suggests that an additional constraint seems to regulate the good behavior of PRF models. Indeed, as we have seen, the best PRF model we have studied favors feedback terms with a high document frequency in the feedback set, whereas the other models we studied fail to do so. This constraint can be formalized as follows:

PRF Heuristic Constraint 2. [Document Frequency] Let $\epsilon > 0$, and $a$ and $b$ two words such that:

1) $1DF(a) = 1DF(b)$
2) The distribution of the frequencies of $a$ ($c(a, d)$) in the feedback set is given by:
$$T(a) = (x_1, x_2, ..., x_j, 0, ..., 0)$$
3) The distribution for $b$ is given by:
$$T(b) = (x_1, x_2, ..., x_j - \epsilon, \epsilon, ..., 0)$$
4) $\forall i, x_i > 0$ and $x_j - \epsilon > 0$

Hence, $TF(a) = TF(b)$ and $DF(b) = DF(a) + 1$. Then, the feedback weight function $FW(.)$ is such that $FW(a) < FW(b)$

In other words, $FW(.)$ is locally growing with $DF(w)$. It is possible to define a constraint based on a globally growing function, but this complicates the matter. Furthermore, the above constraints directly captures the intuition put forward for the document frequency behavior. The following theorem allows one to decide whether a given PRF model agrees or not with the document frequency (DF) constraint for a large class of models (as we will see below):

Theorem 1. Suppose $FW$ can be written as:
$$FW(w) = \sum_{d=1}^{n} f(c(w, d))$$
with $f(0) = 0$. The we have:

1) If the function $f$ is strictly concave, then $FW$ meets the DF constraint.
2) If the function $f$ is strictly convex, then $FW$ does not meet the DF constraint.

Proof If $f$ is strictly concave, then the function $f$ is subadditive ($f(a + b) < f(a) + f(b)$). Let $a$ and $b$ be two words satisfying the conditions of the DF constraint. We have:
$$FW(a) = FW(x_1, ..., x_j, 0, ..., 0)_{DF(a)}$$
$$FW(b) = FW(x_1, ..., x_j - \epsilon, \epsilon, ..., 0)_{DF(a) + 1}$$
and:

\[ FW(b) - FW(a) = f(x^1 - \epsilon) + f(\epsilon) - f(x^1) \]

As the function \( f \) is subadditive, we have: \( FW(b) - FW(a) > 0 \). If \( f \) is strictly convex, then \( f \) is superadditive as \( f(0) = 0 \), and a comparable reasoning leads to \( FW(b) - FW(a) < 0 \). □

As we will see in the next section, many recently proposed PRF models follow equation 1, and can be analyzed with the above theorem.

4. Review of PRF Models

4.1. PRF for Language Models

Traditional methods, such as Rocchio’s algorithm, extract terms from feedback documents and add them to the query. The language modeling (LM) approach to information retrieval follows this approach as it extracts a multinomial probability distribution over words from the feedback document set, parametrized by \( \theta_F \). Assuming \( \theta_F \) has been estimated, the LM approach proceeds by interpolating the query language model with \( \theta_F \):

\[
\theta_{q'} = \alpha \theta_q + (1 - \alpha) \theta_F
\] [2]

In practice, one restricts \( \theta_F \) to the top \( tc \) words, setting all other values to 0. The different feedback models then differ in the way \( \theta_F \) is estimated. We review the main LM based feedback models below.

4.1.1. Mixture Model

Zhai and Lafferty (Zhai et al., 2001) propose a generative model for the set \( F \). All documents are i.i.d and each document comes from a mixture of the relevant topic model and the corpus language model:

\[
P(F|\theta_F, \beta, \lambda) = \prod_{w=1}^V (\lambda \theta_{Fw} + (1 - \lambda) P(w|C))^T_F(w)
\] [3]

where \( \lambda \) is a fixed parameter, which can be understood as a noise parameter for the distribution of terms. Finally \( \theta_F \) is learned by optimising the data loglikelihood with an Expectation-Maximization (EM) algorithm. It is trivial to show that this mixture model does not meet the DF constraint, since it is DF agnostic.

4.1.2. Divergence Minimization

Zhai (Zhai et al., 2001) also propose the divergence minimization model:

\[
D(\theta_q | RF) = \frac{1}{|\eta|} \sum_{i=1}^n D(\theta_F \parallel \theta_q) - \lambda D(\theta_F \parallel p(\cdot \parallel C))
\]
where $\theta_{d_i}$ denotes the empirical distribution of words in document $d_i$. Minimizing this divergence gives the following solution:

$$\theta_{FW} \propto \exp \left( \frac{1}{1-\lambda} \sum_{i=1}^{n} \log(p(w|\theta_{d_i})) - \frac{\lambda}{1-\lambda} \log(p(w|C)) \right)$$

This models amounts to the geometric mean of the smoothed document models with a regularization term. Our previous experiments and those of Lv (Lv et al., 2009) show that this model does not perform well. Although it meets the DF constraint (by using a geometric mean leading to a concave function), the IDF effect is not sufficiently enforced, and the model fails to downweight common words, as shown in Table 3. In other words, this model chooses common words which do have a high document frequency, but are not interesting for retrieval.

### 4.1.3. Other Models

A regularized version of the mixture model, known as the regularized mixture model (RMM) and making use of latent topics, is proposed in (Tao et al., 2006) to correct some of the deficiencies of the simple mixture model. RMM has the advantage of providing a joint estimation of the document relevance weights and the topic conditional word probabilities, yielding a robust setting of the feedback parameters. However, the experiments reported in (Lv et al., 2009) show that this model is less effective than the simple mixture model in terms of retrieval performance, for precision and recall. We will thus not study it further here, but want to mention, nevertheless, an interesting re-interpretation of this model in the context of the concave-convex procedure framework (Dillon et al., 2010).

Another PRF model proposed in the framework of the language modeling approach is the so-called relevance model, proposed by Lavrenko et al. (Lavrenko et al., 2001), and defined by:

$$FW(w) \propto \sum_{d \in \mathcal{F}} P_{LM}(w|\theta_d)P(d|q)$$

where $P_{LM}$ denotes the standard language model. Because of its reliance on the language model, the above formulation is compliant with all the classical IR constraints. Furthermore, it corresponds to the form of equation 1 of Theorem 1, with a linear function, which is neither strictly concave nor strictly convex. This model is neutral wrt the DF constraint. As we have mentioned before, it satisfies the DS constraint.

The relevance model has recently been refined in the study presented in (Seo et al., 2010) through a geometric variant, referred to as GRM, and defined by:

$$FW(w) \propto \prod_{d \in \mathcal{F}} P_{LM}(w|\theta_d)^{P(d|q)}$$

Let us first consider the standard language model with Jelinek-Mercer smooting (Zhai et al., 2004): $P_{LM}(w|\theta_d) = (1 - \lambda)P(w,d)_{\theta_d} + \lambda P(w,C)_{\theta_d}$, where $c(w,C)$ denotes the
number of occurrences of $w$ in the collection $C$ and $l_C$ the length of the collection. Let $w_a$ and $w_b$ be two words as defined in constraint DF, and let us further assume that feedback documents are of the same length $l$ and equiprobable given $q$. Then $FW(w_a)$ and $FW(w_b)$ respectively differ on the two quantities :

1. $((1 - \lambda) \frac{c(w_a, d_j)}{l} + \lambda \frac{c(w_a, C)}{l_C})$  
2. $((1 - \lambda) \frac{c(w_a, d_j)}{l} + \lambda \frac{c(w_a, C)}{l_C})(\frac{1 - \lambda}{l} + \lambda \frac{c(w_a, C)}{l_C})$

The second quantity amounts to :

$$((\alpha - \epsilon')(\beta + \epsilon') = \alpha \beta + \epsilon'(\alpha - \beta) - (\epsilon')^2$$

But $\alpha - \beta = (1 - \lambda) \frac{c(w_a, d_j)}{l}$, a quantity which is strictly greater than $(1 - \lambda) \frac{c}{l} = \epsilon'$ by the assumptions of the DF constraint. Thus the GRM model satisfies the DF constraint when Jelinek-Mercer is used. For the Dirichlet smoothing, setting :

$$\alpha = \frac{c(w, d) + \mu p(w|C)}{l + \mu}, \quad \beta = \frac{\mu p(w|C)}{l + \mu}, \quad \text{and} \quad \epsilon' = \frac{\epsilon}{l + \mu}$$

leads to exactly the same development as above. The GRM model thus satisfies the DF constraint for both Jelinek-Mercer and Dirichlet smoothing. The use of the exponent $P(d|q)$ also shows that it satisfies the DS constraint.

### 4.2. PRF under the Probability Ranking Principle

Xu and Akella (Xu et al., 2008) propose an instantiation of the Probability Ranking Principle (PRP) when documents are modelled with a Dirichlet Compound distribution. Instead of relying on the PRP to extract new terms, they propose a generative model of documents. In their PRP framework, relevant documents are assumed to come from a Dirichlet Compound Multinomial (DCM) distribution, the parameters of which will be denoted $\theta_w$. In the feedback process, documents arise from a mixture of Extended DCM distributions. Contrary to the mixture model, the mixing parameter for each document is not fixed. Furthermore, several modifications of the EM algorithm to moderate the bias of the generative approach are used. Those modifications are similar to the regularized mixture model studied in (Tao et al., 2006). One can show that maximizing the EDCM likelihood leads to forget TF information. Only DF matters for the EDCM model. Let $s = \sum_{w=1}^{M} \theta_w$, then $s$ verifies the following fixed-point equation :

$$s = \frac{\sum_{w} DF(w)}{\sum_{d} \Psi(s + l_d) - n\Psi(s)}$$
Once \( s \) is known, the \( \theta_w \) can be obtained directly by:

\[
\theta_w = \frac{DF(w)}{\sum_d \Psi(s + I_d) - n\Psi(s)}
\]

It is then easy to show that maximizing the likelihood of an EDCM model entails the DF constraint.

### 4.3. PRF in Divergence from Randomness (DFR) and Information Models

In DFR and information models, the original query is modified, following standard approaches to PRF, to take into account the words appearing in \( F \) according to the following scheme:

\[
x^{\prime}_q(w) = \frac{x_q(w)}{\max_w x_q(w)} + \beta \frac{\text{Info}_F(w)}{\max_w \text{Info}_F(w)}
\]

where \( \beta \) is a parameter controlling the modification brought by \( F \) to the original query (\( x^{\prime}_q(w) \) denotes the updated weight of \( w \) in the feedback query, whereas \( x_q(w) \) corresponds to the weight in the original query).

#### 4.3.1. Bo2

The standard PRF model in the DFR family is the Bo2 model (Amati et al., 2003), which is defined by:

\[
g_w = (\sum_{d \in F} l_d)p(w|C)
\]

\[
\text{Info}_{Bo2}(w) = \log_2(1 + g_w) + T_F(w) \log_2(\frac{1 + g_w}{g_w})
\]

In other words, documents in \( F \) are merged together. A Geometric probability model measures the informative content of a word. As this model is DF agnostic, it does not entail the DF constraint.

#### 4.3.2. Log-logistic Model

For information models (Clinchant et al., 2010), the average information this set brings on a given term \( w \) is used as a criterion to rank terms, which amounts to:

\[
\text{Info}_F(w) = \frac{1}{n} \sum_{d \in F} - \log(P(X_w > t^d_w|\lambda_w))
\]

The log-logistic model for pseudo relevance feedback is defined by:

\[
t(w, d) = c(w, d)\log(1 + c\frac{\text{avg}_d l}{I_d})
\]

\[
F_W(w) = \sum_{d \in F} [\log(\frac{n_w}{N} + t(w, d)) + \text{IDF}(w)]
\]
As the log is a concave function, the log-logistic model satisfies the DF constraint by theorem 1. Similarly, the SPL model proposed in (Clinchant et al., 2010) satisfies the DF constraint.

Having reviewed several state-of-the-art PRF models wrt to their behavior according to the DF constraint, we now turn to an experimental validation of this constraint.

5. Validation of the DF Constraint

We present here a series of experiments conducted in order to assess whether the DF constraint is a valid constraint in pseudo-relevance feedback. To do so, we first describe the oracle used to escape away from (and thus not being biased by) any given model.

5.1. Oracle

Suppose an oracle could tell the performance of each individual word in a pseudo-relevance feedback setting. Then, one could look at the oracle word statistics (mean TF, mean DF) in order to further validate the DF constraint. However, if we use such an oracle on pseudo-relevance feedback sets, there will likely be a significant variation of these statistics, since there is a significant variation in the precision at 10. Indeed, it is difficult to compare the TF statistics for a query with \( P@10 = 0.1 \) and for a query such that \( P@10 = 0.9 \). It is difficult to observe a global tendency in such a case. It is however possible to overcome the query variation performance by using true relevance feedback. The experimental setting we follow is thus defined as :

- Start with a first retrieval with a Dirichlet language model;
- Select the first 10 relevant documents if possible, else select the top \( R_q (R_q < 10) \) relevant documents;
- Construct a new query (50 words) with the mixture model;
- Construct a new query (50 words) with the log-logistic model;
- Compute statistics for each word in the new queries.

Statistics include a normalized \( DF \), equal to \( DF(w)/R_q \), and a normalized \( TF \) statistics (the \( TF \) is divided by the actual number of document used for relevance feedback, \( R_q \)). Each word \( w \) is added independently with weights predicted by the retained PRF model. For each word \( w \), we measure the MAP of the initial query augmented with this word. The difference in performance with the intial query can be computed as : \( \Delta(MAP) = MAP(q + w) - MAP(q) \). We thus obtain, for each term, the following statistics :

- \( \Delta(MAP) \)
- \( log(1 + TF(w))/R_q \)
- \( DF(w)/R_q \)
5.2. Experimental Validation

Theorem 1 can help us further validate the DF constraints. Indeed, let us use the family of feedback functions defined by:

$$FW = \sum_{d \in F} t(w, d)^k IDF(w)$$ [8]
Analysis of Pseudo-Relevance Feedback

Figure 2. \((\log(TF),DF)\) vs \(\Delta MAP\) on TREC-12; true relevant documents are used with \(n = 10, tc = 50\) and exponential (left) and Gaussian (right) kernel grids (15 × 15). Top row: log-logistic; bottom row: language model

with \(t(w,d) = c(w,d) \log(1 + \frac{\text{avg}_l d}{w})\), which corresponds to the second DFR normalization. Equation 8 amounts to a standard d \(\text{df-idf}\) weighting, with an exponent \(k\) which allows one to control the convexity/concavity of the feedback model. According to Theorem 1, if \(k > 1\) then the function is strictly convex and does not satisfy the DF constraint. If \(k < 1\), then the function is strictly concave and satisfies the DF constraint, while the linear case, being both concave and convex, is in-between. We can then build PRF models from equation 8 with varying \(k\), and see whether the results agree with the theoretical findings implied by Theorem 1. We used these PRF models with equation 5 and a log-logistic model to assess their performance (as the log-logistic model was the best performing model in our preliminary experiments). Table 5 displays the term statistics (\(\mu(tf), \mu(df)\), mean IDF) for different values of \(k\). As one can note, the smaller \(k\), the bigger \(\mu(df)\) is. In other words, the slowerlier the function grows, the more terms with large DF are preferred. Table 6 displays the MAP for different values of \(k\). At least two important points arise from the results obtained. First, convex functions (\(k > 1\)) have lower performance than concave functions for all

datasets, as predicted by the DF constraint and Theorem 1. As convex functions do not entail the DF constraint, this suggests that the DF constraint is valid and leads to better performance. Second, the square root function \((k = 0.5)\) has the best performances on all collections: it also outperforms the standard log-logistic model. When the function grows slowly \((k \text{ equals to } 0.2)\), the DF statistics is somehow preferred compared to TF. The square root function achieves a different (and better) trade-off between the TF and DF information. This is an interesting finding as it shows that the TF information is still useful and should not be too downweighted wrt the DF one.

6. Conclusion

We have studied in this paper the behavior of several PRF models, and have displayed their main characteristics through a first series of experiments. This led us (a) to show that the divergence minimization PRF model was deficient wrt the IDF effect (i.e. this model selects terms with large IDF), and (b) to introduce a new heuristic constraint for PRF models, referred to as the Document Frequency (DF) constraint. We have then analyzed, from a theoretical point of view, state-of-the-art PRF models according
Analysis of Pseudo-Relevance Feedback

to their relation with this constraint. This analysis revealed that the standard mixture model for PRF in the language modeling family does not satisfy the DF constraint.

We have then conducted a series of experiments in order to see whether the DF constraint is valid or not. To do so, we performed tests with an oracle and a simple family of tf-idf functions based on a parameter k controlling the convexity/concavity of the function. Both the oracle and the results obtained with this family of functions validate the DF constraint. Furthermore, our experiments suggest that the square root function should be preferred over the mean log-logistic information model introduced in (Clinchant et al., 2010) for pseudo-relevance feedback, as the square root function achieves a better tradeoff between the DF and TF statistics.
