Abstract

This report presents the synthesis of copper cadmium ferrite ($\text{Cu}_{1-x}\text{Cd}_x\text{Fe}_2\text{O}_4$, $x = 0.3$, 0.4, 0.5, 0.6 and 0.7) by citrate precursor method and its subsequent characterization by using X-ray diffraction (XRD), differential scanning calorimetry, infrared spectroscopy and ferromagnetic resonance. XRD results confirm the single cubic spinel phase formation with the particle size of 40 nm, which decreased up to 20 nm with increase in Cd content, while the lattice parameter increased with increase in Cd content. A significant change in the magnetic properties was observed in CuFe$_2$O$_4$ system with Cd doping. The line width and resonance field variation against change in temperature is noted and the data is fitted to the Linearized model (LM) and Smit and Beljers (SB) model to find out the parameters. The results recorded from the SB approach are in good agreement to that observed in the magnetic measurements carried out by vibrating sample magnetometer (VSM) techniques.

1. Introduction

The synthesis of nanostructured magnetic materials has become an important area of research since such materials are attracting growing interest in technological applications of modern magnetic materials which reveal a range of fascinating phenomena [1–4]. Especially, nanoscale magnetic ferrites are of particular interest due to their unique combination of electronic and magnetic properties [4–6]. Transition metal oxides (MFe$_2$O$_4$) are magnetic materials with cubic spinel structure and have been extensively used in various technological applications in the past decade. Indeed, owing to their high electrical resistivity that implies low losses due to parasitic currents, and to their susceptibility, they are preferred in application ranging from transformers to magnetic heads. In addition, their high permeability in the r.f. frequency region, make polycrystalline ferrites suitable for an increasing number of electronic devices [7]. Cubic spinel ferrites with space groups Fd3m, have been the subject of many recent investigations due to cation distribution. The diversity in properties of ferrites has paved the way for the development of a wide variety of ferrites for various applications as permanent magnets, electrical and electronic compounds. Copper ferrite is an inverse ferromagnetic spinel in which a small amount of Cu$^{2+}$ ions migrate from octahedral B to tetrahedral A sites. The degree of inversion (Cu$_{x}$Fe$_{1-x}$)$_{A}$[Cu$_{1-x}$Fe$_{1+x}$]$_{B}$O$_4$, (where $\delta$ is the inversion parameter and $\delta = 0$ and 1 stand for the inverse and normal cases, respectively) i.e the fraction of cupric ions at B-sites strongly depends on the preparation technology [8–10]. Incorporation of zinc and cadmium ions strongly affects the magnetic properties of ferrospinel [11] due to its well known preferences for tetrahedral surroundings. It has been reported that cadmium substituted Cu ferrites behaves as n-type semiconductors and the seebeck coefficient gradually decreases with increase in cadmium content [12, 13]. The physical and chemical properties of these materials can be tuned by controlling the particle size, shape and the inter particle interactions [14–17].

Ferromagnetic resonance (FMR) is a spectroscopic technique to probe the magnetization of ferromagnetic materials. It is a standard tool for probing spin waves and spin dynamics, so it is a powerful characterization technique for magnetic nanoparticle systems [18–22]. One of the advantages of FMR over
conventional magnetization measurements is that it yields information on the dynamics of the system. FMR gives contribution from the each component in the assembly. This is a powerful tool in probing mixture systems with ferro/ferri and paramagnetic particles. The temperature variation of the FMR spectra provide valuable information on magnetic systems, especially in an assembly of magnetic nano particles. One of the first attempts to understand the temperature variation of the FMR spectra was done by Biasi and Devezas [18]. More recently Raikher and Stepanov [23] developed a formalism to consider superparamagnetic resonances in the limit of large Zeeman interaction as compared to the anisotropy energy. They reported that the shape anisotropy has the same functional dependence as a uniaxial anisotropy term, which is different from what was originally predicted [20]. Only recently [21-23] these theories have been applied to systems to obtain the physical parameters like anisotropy and magnetic moment, from the line shape of the FMR curves. In one such attempt, while probing Co/Ag clusters, Sánchez et al. [22] showed that FMR and DC magnetization yield consistent results regarding the particle volume and anisotropy. These theories rely on the assumption that the effective field acting on each particle can be considered as the addition of the applied field and the anisotropy field modified by thermal excitations. However, large volume systems, such as thin films, where the resonance field is non-linear in the applied field [24-25] these theories cannot be directly applied.

In a recent publication, E. de Biasi et al. [26] has given detailed information on thermal fluctuations in the FMR modeling of ferromagnetic single domain nanoparticles with uniaxial shape anisotropy in which the results obtained from the nonlinear SB model and LM model were compared assuming the $\Delta H_0$ as a constant near to room temperature and high temperature. The paper provides emphasis on the interpretation of the observed quantities (FMR line shape, line width and resonance field) in terms of the particle parameters (magnetic moment, anisotropy, and intrinsic FMR line width).

From the simulations performed in the abovementioned article, it is clear that the usual “peak-to-peak” line width, $\Delta H_{pp}$ obtained from the FMR spectra is not unambiguously defined at low temperature, as there are two peaks in the low (high) field side for the prolate (oblate) ellipsoid. For the purpose of deriving the
anisotropy from observed line width, $\Delta H_{pp}$ should be obtained from the peaks most widely separated. The results obtained from the Smit–Beljers (SB) formulation is compared with a linearized model for the resonant field. In the limit of small anisotropy both results coincide. At moderate and large anisotropy the RMS deviation indicates clear discrepancies between these two models. In that it is shown that the anisotropy field can be directly deduced from the low temperature peak-to-peak line width analysis and the particle magnetic moment can be estimated after subtraction of the intrinsic line width contribution. In our system of Cd doped copper ferrite, FMR signal and resonance field was recorded at different temperatures. Authors followed a similar approach as provided in [26] for the calculation of $\Delta H_{pp}$, anisotropy and magnetic moment. The line shape observed in our system exactly follows the simulated curves for the prolate ellipsoid [25] in which the line doubling is more towards the low field side.

In the present investigation we have prepared nano structured Cu$_{1-x}$Cd$_x$Fe$_2$O$_4$ (where $x = 0.3$, 0.4, 0.5, 0.6 and 0.7) system through thermal decomposition of mixed metal citrates. We attempt to determine the effect of copper ferrite spinel formation and the role of cadmium content on structural and magnetic properties of these ferrospinsels.

2. Experimental details
2.1 Materials Synthesis

Polycrystalline samples of Cu$_{1-x}$Cd$_x$Fe$_2$O$_4$ with $x = 0.3$, 0.4, 0.5, 0.6 and 0.7 were prepared by citrate precursor method. The technological advantage of this method is that mixing of the metal ions takes place on an atomic scale in the solution state during the initial stages of preparation giving rise to homogeneous mixtures. The chemical precursors used in the preparation were copper nitrate, cadmium nitrate, Iron (III) nitrate and citric acid. The chemicals were accurately weighed according to the required stoichiometric proportion. An aqueous solution of Fe (III) citrate was prepared in distilled water. Copper nitrate and Cadmium nitrate was separately mixed with citric acid and few drops of distilled water and heated at about 40°C for an hour to form the metal-citrate complex. These solutions were then added slowly to the Fe (III) citrate solution with constant
stirring to avoid precipitation and obtain a homogeneous mixture. The clear solution of brown-colored citrate mixture was obtained with no precipitation and no segregation of phases. This mixture was gradually heated at 60°C on a hot plate with magnetic stirrer to obtain slurry. The precursor was obtained by drying it in the oven. This solid precursor was in the form of a uniformly colored brown transparent glassy material containing the cations homogeneously mixed on an atomic scale [27]. This dried citrate mixture was calcined in muffle furnace for 4 hours at 600°C to obtain a ferrite of the compound Cu1-xCdxFexO4. The calcined compounds were grounded in a mortar pestle to obtain fine powder. The fine powders were used to characterize the structural and magnetic properties of the compound.

2.2 Structural Characterization

The X-ray diffraction pattern of the compounds was recorded at room temperature using X-ray powder diffractometer with CuKα radiation (λ = 1.5418 Å) in a wide range of Bragg angles 2θ (20° ≤ 2θ ≤ 60°) at a scanning rate of 2° min⁻¹. Fourier Transform Infrared (FTIR) spectra of dried samples were recorded on the Thermo NICOLET 5700 FTIR spectrophotometer in the range of 4000–400 cm⁻¹ in ATR (attenuated total reflectance) mode.

2.3 Magnetic Characterization

FMR measurements were done using an X-band electron paramagnetic resonance spectrometer Bruker ESP 300 E. The resonance spectra were recorded in varying magnetic field mode for the Cd doped copper ferrite samples at a constant microwave frequency of 9.48 GHz. The other parameters are: microwave power= 0.5 mW; Gain= 1x10²; Cylindrical quartz sample holder. The recording of the resonance spectra were repeated for different temperatures starting from 125K to 400K in a step of 10K in order to study the variation of the line shape, resonance field and line width with respect to the change in temperature. The magnetic data were recorded with the help of vibrating sample magnetometer (VSM) (Cryogenic).

2.4 Thermal Characterization
Differential Scanning Calorimetry (DSC) and Thermal Gravimetric Analysis (TGA) studies were carried out from room temperature to 800°C at a heating rate of 5°C/min by NETZSCH (GMBH). STA449C software was used for the analysis of these studies.

3. Results and discussion

3.1 Structural Analysis

The X-ray diffractograms of Cu_{1-x}Cd_{x}Fe_{2}O_{4} ferrite system (Fig. 1) reveal the single-phase spinel structure without any ambiguous reflection. The experimentally observed d spacing values and relative intensities are in well agreement with those reported in the ASTM powder diffraction files. The calcined powder samples show XRD peaks at \( d = 2.97, 2.59, 2.50, 2.06 \) and 1.59 Å and they are in good agreement with the standard XRD pattern, JCPDS (34-0425) of CuFe_{2}O_{4}. The lattice parameters are obtained by fitting at least seven diffraction peaks using standard least square refinement methods. The lattice parameters are in the expected range with the lattice constant of CuFe_{2}O_{4} [28] and CdFe_{2}O_{4} [29] at either end. Lattice parameter increases linearly with the increase of cadmium content. This could be attributed, as expected, to the large ionic radius of Cd\(^{2+}\) (0.78 Å\(^{\circ}\)) which when substituted in the lattice resides on the tetrahedral site and replaces the smaller Cu\(^{2+}\) (0.57 Å\(^{\circ}\)) or Fe\(^{3+}\) (0.49 Å\(^{\circ}\)) ions from the tetrahedral to the octahedral site [30-31]. No other phase was observed in the XRD pattern indicating that no chemical transformation took place during the heat treatment. The XRD graph indicated that the synthesized powders contain nanosized crystallites. The variation of average particle size and lattice parameter with Cd content is shown in Fig. 2. The average particle size decreases with Cd content, which is attributed to the diffusion phenomenon involving Cd, oxygen vacancies and porosity that hampers the grain growth.

3.2 FTIR Analysis

Fig. 3 shows FTIR spectrum recorded from the dried powder of CuCdFerrite prepared by citrate precursor method. The representative spectra of nanoparticles obtained manifests absorption peaks located at about 1160, 1236, 1309, 1434, 1614 and 1722 in the region of 1000-1750 cm\(^{-1}\). The absorption peak at around
1160-1309 cm$^{-1}$ can be assigned as absorption peaks of aliphatic amines. The peaks at 3400 cm$^{-1}$ and 2900 cm$^{-1}$ were assigned to the stretching vibrations of primary and secondary amines. The as-synthesized sample shows characteristic absorptions of ferrite phase with a strong absorption around 1600 cm$^{-1}$ and weak absorption in the range 1000-1450 cm$^{-1}$. This difference between the band positions is expected because of the difference in the Cd$^{+}$ - O$_{2}^{-}$ distance for the octahedral and tetrahedral compounds. There are weak and broad absorptions around 2800 and 3500 cm$^{-1}$ corresponding to the presence of small amount of residual carbon in the samples. Heat treatment led to the disappearance of these absorptions indicating complete removal of residual carbon from the sample.

3.3 Thermal Analysis

The thermal decomposition studies of the samples shows that all the mixtures decompose in the temperature range 40$^0$C to 350$^0$C. A typical DTA-TG thermogram for the thermal decomposition of CuCdFe$_2$O$_4$ in air is shown in Fig. 4. It can be observed that the mixture loses its weight in three well defined steps giving at complete decomposition a total weight loss of 85% which corresponds to the formation of copper cadmium ferrite; CuCdFe$_2$O$_4$. The first step starts at 40$^0$C and is characterized by an endothermic peak at 80$^0$C. The weight loss that accompanied this step amounts to 20% on the TGA curve due to vaporization of water. The mixture is thermally stable upto 140$^0$C after which the main decomposition step occurs. This step exhibits a weight loss of 40% at 150$^0$C which closely corresponds to the complete decomposition of iron (III) nitrate with the formation of Fe$_2$O$_3$. The endothermic DTA peak at 140$^0$C was swamped by the large exothermic decomposition occurring at 150$^0$C. The third step accounts for the exothermic decomposition of copper nitrate and cadmium nitrate with the formation of CuO and CdO, respectively. This step is associated with 25% weight loss at 264$^0$C. No further weight loss was observed even by raising the temperature upto 800$^0$C.

3.4 Magnetic Resonance Analysis
One of the typical characteristic of a resonance spectrum is the resonance field, \( H_r \). The resonance spectra (the first derivative of the microwave power absorption) of \( \text{Cu}_{1-x}\text{Cd}_x\text{Fe}_2\text{O}_4 \) as a function of the magnetic field in different temperatures are shown in Fig. 5 (a,b,c), where \( x \) varies from 0.3 to 0.7. Resonance field is determined by fitting the experimental resonance line to Lorentzian (derivative) curve. The temperature dependence of the apparent peak-to-peak line width and that of the apparent resonance field for all the samples are given in Fig. 6 and Fig. 7 respectively. It is observed that as the temperature decreases the spectra are broadened and their apparent centre shifts towards lower magnetic fields (Fig. 6-8). A marked decrease in the peak-to-peak amplitude is observed at the same time. The observations are similar to that reported earlier in gamma \( \text{Fe}_2\text{O}_3 \) system [32]. This behaviour is typical of a superparamagnetic particle (Normally the resonance field is a function of the magnetic moment of the sample which increases with cooling as thermal randomisation is less. Hence the resonance field is expected to increase with the decrease in temperature). In the case of a random distribution of anisotropy axes each nanoparticle has its own \( H_r \). Therefore, the resonance field of an ensemble of randomly oriented non-interacting particles cannot be clearly defined in the spectrum. Many previous works report \( H_r \) to decrease when \( T \) is lowered in nanoparticle systems. In an attempt to explain the observation of the reduction of \( H_r \) from the \( o = g \) value, Berger et al.[33] proposed that this effect is due to the damping of the magnetization, finding the Landau–Lifshitz equation to best describe the observed spectra. Verdes et al. [34] showed with the help of monte carlo simulations that exchange effects can give a significant shift in the resonance line, in all cases lowering the observed resonance field.

One can see in Fig. 8 that both the resonance field and the line width can be fitted by assuming Lorentzian (derivatives) except for small discrepancies showing the absence of other phases in the sample: The discrepancy could be due to the neglect of the temperature dependence of the magnetic parameters \( M \) and \( K_1 \) (first-order anisotropy constant). The apparent peak-to-peak line width variation with temperature is shown in Fig. 6. The temperature dependence of the individual line width is rather complicated. At very low temperatures the Langevin function becomes saturated for the majority of the nano particles so that the main
mechanism of this dependence is the thermal fluctuation induced modulation of the magnetocrystalline
anisotropy energy.

\[ \Delta T = \Delta_0 G \left( \frac{K_i V_s}{kT} \right) \]

provides a good estimate of the experimental low temperature line widths. The \( \Delta_T \) value at \( T = 0 \) (the
greatest limiting line width \( \Delta_0 \), corresponds to the relaxation frequency \( 5.3 \times 10^9 \) s\(^{-1}\) (biggest nanoparticle in the
statistical assembly under consideration have a diameter of 230 Å). This value of relaxation frequency can be
compared to that of the reported value for gamma Fe\(_2\)O\(_3\) at low temperature [26].

\( \Delta H_{pp} \) was plotted for all the samples considering the most widely separated peaks (the lowest maximum
and the minimum) for a prolate ellipsoid as a function of \( H_A \) for different intrinsic widths SB(bottom) approach
[26]. The line shape and the temperature variation of the line shape, resonance field and the peak to peak line
width exactly follows the simulated curves for a prolate ellipsoid by the SB approach [26]. So the most relevant
one is the temperature variation of the peak-to-peak width. Hence the exchange effects are not considered in the
calculations.

**Fig. 7** provides experimental recording of \( \Delta H_{pp} \) as a function of temperature for different compositions
of Cd doped copper ferrite samples. At high temperature \( \Delta H_{pp} \) approaches asymptotically the intrinsic width
value, corresponding to a Lorentzian line shape. Therefore from experiments \( \Delta H_0 \) and \( \mu \) can be extracted
(Table 1). For the calculation of \( \mu \) and \( \Delta H_0 \), from \( \Delta H_{pp} \), the simple LM approach was adopted. Assuming \( \Delta H_0 \)
constant in the high-T limit, the observed \( \Delta H_{pp} \) had a \( 1/T^2 \)-dependence, from which \( \mu \) is determined [26] for all
the copper ferrite samples with varying cadmium concentrations. The values of the magnetic moment and the
anisotropy field are very much in agreement with the values calculated from the VSM data (Table 1). Hence the
analysis of the FMR signal in a system with varying magnetic moment shows that the SB approach can be used
for the determination of an ensemble of magnetic particles especially in ferrites with more or less homogeneous particle size or with a system with very small variation in the particle size.

4. **Conclusions**

We have reported the structural, microstructural and FMR properties of cadmium doped copper ferrite ceramics, which was synthesized by citrate precursor method. The average particle size of copper ferrite was 40 nm, which on doping with Cd decreased to 20 nm. Thermal treatment of the ferrite samples led to the disappearance of the absorption peaks in the DSC study indicating the complete removal of residual carbon from the sample. All the samples exhibited ferromagnetic nature at room temperature with appreciable value of remanent magnetization. Switching of magnetic moments from a higher value to zero is observed for all the samples at a specific applied magnetic field. The line width and resonance field variation against change in temperature is fitted with the LM and SB model. A system with varying magnetic moment (Cd doped copper ferrite which is pre-characterised magnetically by VSM) is used as a nanoparticle system. The results recorded from the SB approach are in good agreement to that observed in the magnetic measurements by VSM. The anisotropy field was directly deduced from the low temperature peak-to-peak linewidth analysis and the particle magnetic moment was estimated after substraction of the intrinsic linewidth contribution. FMR signal in a system with varying magnetic moment shows that the SB approach can be used for the determination of an ensemble of magnetic particles especially in ferrites.

Abstract

This report presents the synthesis of copper cadmium ferrite (Cu$_{1-x}$Cd$_x$Fe$_2$O$_4$, x = 0.3, 0.4, 0.5, 0.6 and 0.7) by citrate precursor method and its subsequent characterization by using X-ray diffraction (XRD), differential scanning calorimetry, Infrared spectroscopy, Ferromagnetic resonance and vibrating sample magnetometer (VSM) techniques. XRD results confirm the single cubic spinel phase formation with the particle size of 40 nm, which decreased up to 20 nm with increases in Cd content, while the lattice parameter increased with increase in Cd content. A significant change in the magnetic properties was observed in CuFe$_2$O$_4$ system with Cd doping. The line width and resonance field variation against change in temperature is noted and the data is fitted to the Linearized model (LM) and Smit and Beljers (SB) model to finds out the parameters. A system with varying magnetic moment Cd doped copper ferrite were used as a nanoparticles system. The results recorded from the SB approach are quite in good agreement to that is observed in the magnetic measurements carried out by VSM.
Highlights PCS_6440

1. Copper cadmium ferrite compounds prepared by citrate precursor method.
2. XRD results confirm the single cubic spinel phase formation with the particle size of 20 nm,
3. The lattice parameter increased with increase in Cd content.
4. A significant change in the magnetic properties was observed in CuFe2O4 system with Cd doping.
