We report on magnetization and electron spin resonance (ESR) measurements of Sr\textsubscript{2}VO\textsubscript{4} with orthorhombic symmetry. In this dimer system the V\textsuperscript{4+} ions are in tetrahedral environment and are coupled by an antiferromagnetic intra-dimer exchange constant \( J/k_B \approx 100 \text{ K} \) to form a singlet ground state without any phase transitions between room temperature and 2 K. Based on an extended-Hückel-Tight-Binding analysis we identify the strongest exchange interaction to occur between two inequivalent vanadium sites via two intermediate oxygen ions. The ESR absorption spectra can be well described by a single Lorentzian line with an effective g-factor \( g = 1.89 \). The temperature dependence of the ESR intensity is well described by a dimer model in agreement with the magnetization data. The temperature dependence of the ESR linewidth can be modeled by a superposition of a linear increase with temperature with a slope \( \alpha = 1.35 \text{ Oe/K} \) and a thermally activated behavior with an activation energy \( \Delta/k_B = 1418 \text{ K} \), both of which point to spin-phonon coupling as the dominant relaxation mechanism in this compound.

I. INTRODUCTION

Quantum magnetism is a fascinating research field with a plethora of observed and predicted exotic phenomena such as the Bose-Einstein condensation of magnons\textsuperscript{1} or quantum spin-liquids\textsuperscript{2}. In transition-metal oxides where the magnetic ions are in 3\textit{d} or 3\textit{d}\textsuperscript{5} electronic configuration with spin \( S = 1/2 \) such as, for example, Cu\textsuperscript{2+} cuprates, T\textit{j}\textsuperscript{3+} in titanates or V\textsuperscript{4+} in vanadates, the coupling of spin, orbital, and lattice degrees of freedom makes the ground-state properties particularly rich and complex\textsuperscript{2,3}.

In this study we will focus on orthorhombic Sr\textsubscript{2}VO\textsubscript{4}, where the V\textsuperscript{4+} ions are in 3\textit{d}\textsuperscript{1} configuration and the electron occupies the low-lying \( e \)-states in tetrahedral environment as sketched in Fig. 1. The material exhibits orthorhombic symmetry with space group \( Pn\overline{a}2_1 \) and lattice parameters \( a = 14.092(4) \text{ Å} \), \( b = 5.806(2) \text{ Å} \), and \( c = 10.106(3) \text{ Å} \) (see Fig. 1).\textsuperscript{4} The orthorhombic distortion can be interpreted in terms of a Jahn-Teller distortion which removes the orbital degeneracy of the V\textsuperscript{4+} ions. No phase transitions have been observed in the temperature range from 4 to 300 K for orthorhombic Sr\textsubscript{2}VO\textsubscript{4}. Its susceptibility has been described in terms of a spin-dimer system with a singlet ground state and an antiferromagnetic intra-dimer coupling of about 100 K\textsuperscript{10}. However, a clear identification of the superexchange paths corresponding to the magnetic intra-dimer coupling is not available at present, because the superexchange paths between the structural VO\textsubscript{4} units will involve two or more ligands. Such more complicated super-exchange (SSE) paths have been found to yield exchange couplings of considerable magnitude and to determine the ground state properties in a large number of compounds\textsuperscript{11–14}.

Here we investigate orthorhombic Sr\textsubscript{2}VO\textsubscript{4} by magnetization and electron spin resonance experiments. The exchange paths are analysed by an extended-Hückel-Tight-Binding (EHTB) approach and one dominant exchange path via two intermediate oxygen ions is identified. The ESR intensity confirms the dimer-picture for the susceptibility, the spin-orbit coupling is estimated from the effective g-factor, and the linewidth seems to be governed by a phonon-mediated relaxation mechanism and a thermally activated process.

II. EXPERIMENTAL DETAILS

Ceramic samples were prepared from a Sr\textsubscript{4}V\textsubscript{2}O\textsubscript{9} precursor\textsuperscript{5} by four consecutive reduction and grinding processes at 1100 C in sealed quartz tubes with metallic Zr as an oxygen getter. The samples were characterized by X-ray powder diffraction and showed good agreement with the reported symmetry and lattice parameters\textsuperscript{10}. Susceptibility measurements were performed using a SQUID magnetometer (Quantum Design). ESR measurements were performed in a Bruker ELEXSYS E500 CW-spectrometer at X-band frequencies (\( \nu \approx 9.47 \text{ GHz} \)) equipped with a continuous He-gas-flow cryostat in the temperature region 4 < \( T < 300 \text{ K} \). ESR detects the power \( P \) absorbed by the sample from the transverse...
magnetic microwave field as a function of the static magnetic field \( H \). The signal-to-noise ratio of the spectra is improved by recording the derivative \( dP/dH \) using lock-in technique with field modulation.

### III. EXPERIMENTAL RESULTS AND DISCUSSION

#### A. Magnetic Susceptibility

Let us now consider the susceptibility of \( \text{Sr}_2\text{VO}_4 \) as shown in Fig. 2 This system has been described previously as a system of antiferromagnetically coupled spin-dimers with a singlet ground state. To analyze the susceptibility \( \chi = M/H \) determined from the magnetization \( M \) divided by the applied magnetic field \( H \) in the entire temperature range we use

\[
\chi = \chi_0 + \chi_C + \chi_{BB},
\]

with a Curie contribution \( \chi_C = C/T \) due to unbound spins and magnetic impurities and a constant contribution \( \chi_0 \), and the dimer susceptibility \( \chi_{BB} \) as derived by Bleany and Bowers,

\[
\chi_{BB}(T) = \frac{Ng^2\mu_B^2}{k_BT}[3 + \exp(J/k_BT)]^{-1}.
\]

Here \( J \) denotes the intradimer exchange coupling, \( g \) is the effective \( g \)-factor of the vanadium ions, and \( \mu_B \) is the Bohr magneton. The \( g \)-factor was fixed to the experimental value \( g = 1.89 \) observed in the ESR measurements (see below). The obtained fit parameters are \( J = 104 \, \text{K} \), \( \chi_0 = 1.10^{-4} \, \text{emu/mol} \), which is of the typical order of magnitude for a diamagnetic contribution, and \( C = 0.028 \, \text{emuK/mol} \), corresponding to about 7% of unpaired spins. The value for the intradimer exchange \( J = 104 \, \text{K} \) is in agreement with literature\(^{10}\) and corresponds nicely to a magnetic excitation peaked at 8.6 meV observed by neutron scattering\(^{16}\). From the structural arrangement, however, it is not clear which of the possible exchange paths corresponds to this dominant exchange-coupling constant. Therefore, we performed an extended Hückel-Tight-Binding analysis of the exchange paths which will be discussed in the following.

#### B. Analysis of the exchange paths

Six distinct exchange paths with exchange couplings \( J_0-J_5 \) and increasing distance between the vanadium ions can be identified in the structure of \( \text{Sr}_2\text{VO}_4 \) (see Fig. 3 and Table I). The interaction between the magnetic orbitals of two ions in a spin dimer gives rise to two molecular orbitals with an energy split \( \Delta \). In the spin-dimer analysis based on EHTB calculations\(^{11,17}\), the strength of an antiferromagnetic exchange interaction between two spin sites is estimated by \( J_{AF} = -(\Delta \epsilon)^2/U_{eff} \), where \( U_{eff} \) is the effective on-site repulsion that is nearly constant for a given compound.

Double-\( \zeta \) Slater-type orbitals are adopted to describe the atomic \( s \), \( p \), and \( d \) orbitals in the EHTB calculations. The atomic parameters used for the present EHTB calculations of \( (\Delta \epsilon)^2 \) are summarized in Table II. The parameters of V and O atoms are referred to the previous EHTB calculations on other vanadate compounds\(^{18}\) while the rest are taken from the atomic orbital calculations\(^{11,19}\).

As suggested in Ref.\(^{17}\), the exchange paths between neighboring vanadium atoms could be V–O–O–V or V–
Ref. 20 was used. For the calculation of the off-diagonal matrix elements $H_{ij}$, the weighted formula as described in Ref. [15] was used. $C$ and $C'$ denote the contraction and diffuse coefficients used in the double-$\zeta$ Slater-type orbitals.

TABLE I. Exponents $\zeta_i$ and valence shell ionization potentials $H_{ii}$ of Slater-type orbitals $\phi_i$ used for extended Hückel tight-binding calculations. $H_{ii}$ are the diagonal matrix elements $\langle \phi_i | H_{eff} | \phi_i \rangle$, where $H_{eff}$ is the effective Hamiltonian. For the calculation of the off-diagonal matrix elements $H_{ij} = \langle \phi_i | H_{eff} | \phi_j \rangle$, the weighted formula as described in Ref. [21] was used. $C$ and $C'$ denote the contraction and diffuse coefficients used in the double-$\zeta$ Slater-type orbitals.

The exchange paths between second- to sixth-nearest neighboring pairs of V ions are significantly increased, when the strontium atoms are considered in the exchange paths. Therefore, the exchange paths are chosen as V–O–Sr–O–V for $J_0$, $J_1$, $J_2$, $J_3$, $J_4$, and $J_5$ (see Fig. 3(c)-(g)). In contrast, strontium atoms are not considered for the exchange path $J_0$.

The results of our calculations are summarized in Table III. It shows that the dominant spin-dimer exchange is mediated by the path corresponding to $J_0$ (see Fig. 3(b)), where the distance between two V ions is shortest. It is interesting that the second strongest exchange is not between the second-nearest-neighbor V ions, but mediated along the path with $J_2 = 0.15J_0$.

C. Electron Spin Resonance

The absorption spectra of Sr$_2$VO$_4$ can be described by an exchange-narrowed Lorentzian line shape as shown in the inset of Fig. 3(c). The temperature dependences of the obtained fit parameters are shown in Fig. 3.

The temperature dependence of the ESR intensity $I_{ESR}$ can be well fitted by using Eq. II (solid line in Fig. 3(a)) and yields a slightly larger exchange constant $J = 107$ K. The experimental effective $g$-factor of 1.89 as shown in Fig. 3(b) was used and $\chi_0$ was set to zero, because it does not contribute to the resonance absorption. These parameters are in agreement with the fit for $M/H$ and show that the resonance absorption originates from magnetic-dipole allowed intra-triplet excitations with $\Delta S_z = \pm 1$ (see inset of Fig. 2). The increase of the $g$-factor and the decrease of the ESR linewidth below 30 K signal the depopulation of the excited triplet state and the ESR intensity should drop to zero in the ground state. Instead, the intensity increases towards lower temperatures in a Curie-like fashion (solid points) indicating that the resonance signals at lowest temperatures with $g = 1.94$ and $\Delta H = 156$ Oe belong to unpaired paramagnetic ions in the sample.

For the intra-triplet excitations (open symbols) we find an almost temperature independent $g$-factor $g = 1.89$ between 50 and 150 K. The decrease towards higher temperatures is probably related to the increasing linewidth, which reaches the order of magnitude of the resonance field above 200 K and, hence, imposes a larger uncertainty on the resonance field (or $g$-factor) as a fitting pa-
The temperature dependence can be well described by a coth(\(h\omega_{ph}/k_BT\))-behavior which yields a linear behavior for \(h\omega_{ph}/k_BT \ll 1\). Hence, any possible source of line-broadening such as a Jahn-Teller distortion of the system could be the origin of the linear contribution. We want to mention that we have no indication of the presence of a sizeable static DM interaction. However, there is no center of inversion between the two inequivalent V sites and a static DM contribution within the dimers could arise.

A thermally activated contribution has been observed for several low-dimensional magnets and in the dimer system \(\text{Sr}_3\text{Cr}_2\text{O}_6\), where the \(\text{Cr}^{2+}\) also have an electronic 3d\(^1\) configuration in a tetrahedral crystal field. In the latter compound the value of \(\Delta = 388\) K is lying within the phonon frequency range and the contribution was tentatively assigned to stem from a two-phonon Orbach process, where the spin relaxation occurs via an absorption of a phonon to a higher-lying electronic state in the energy range of the phonon continuum. For \(\text{Sr}_2\text{VO}_4\) the value \(\Delta = 1418(19)\) K is too high for phonon modes and rules out the presence of an Orbach mechanism. Since all of the mentioned studies deal with Jahn-Teller active ions, another possible origin of such a thermally activated behavior could be the presence of different Jahn-Teller distortions, which are close in energy, e.g. in case of the one-dimensional magnet \(\text{CuSb}_2\text{O}_6\) (\(\text{Cu}^{2+}\) with spin 1/2 in octahedral environment) the exponential increase of the linewidth with \(\Delta = 1484\) K has been observed on approaching a static-to-dynamic Jahn-Teller transition at 400 K. The value of \(\Delta\) would then correspond to the energy barrier separating the two Jahn-Teller configurations.

The linear term can be understood in terms of a spin-phonon relaxation mechanism, where one phonon is involved in the relaxation process. The relaxation rate depending on the probabilities for absorption and emission of the phonon will follow a coth(\(h\omega_{ph}/k_BT\)) behavior which yields a linear behavior for \(h\omega_{ph}/k_BT \ll 1\).

### IV. SUMMARY

In summary, we investigated orthorhombic \(\text{Sr}_2\text{VO}_4\) by electron spin resonance measurements and identified the dominating exchange path to occur between two inequivalent vanadium sites via two intermediate oxygen ions using an extended-Hückel-tight binding analysis. The temperature dependence of the ESR intensity and the magnetization reveal a dimerized singlet ground state with an intradimer coupling constant \(J/k_B \approx 100\) K. The ESR linewidth exhibits an increase with rising temperature which can be understood in terms of a phonon-modulated spin relaxation yielding a linear increase with slope \(\alpha = 1.35\) Oe/K and a thermally activated Arrhenius behavior with an activation energy \(\Delta/k_B = 1418\) K, which might be related to the Jahn-Teller distortion of the system.
