ABSTRACT: Assembly of paramagnetic Cu₂ complexes with a Schiff base scaffold possessing extended electron delocalization together with a quasi-planar structure onto carbon nanotubes induces a diameter-selective charge transfer from the complex to the nanotubes leading to an interestingly large and tunable ambipolar effect. We used complementary techniques such as electron paramagnetic resonance, absorption spectroscopy, and photoluminescence to ensure the success of the assembly process and the integrity of the complex in the nanohybrid. We carried out density functional theory type calculations to rationalize the experimental results, evidencing the selective enhanced interaction of the metal complexes with one type of nanotube.

INTRODUCTION

Single-wall carbon nanotubes (SWNTs) have been at the forefront in the field of molecular electronics, particularly for design of smart devices such as ultrasensitive probes or field-effect transistors (FET).^{1–4} Combining the unique electronic and optic properties of SWNTs in FETs can even lead to new and guarantee modifications of the carbon nanotube field effect transistor (CNFET) properties.¹⁷ Molecular complexes built using a Schiff base scaffold, well known for their optical, magnetic, and conducting properties, possess the desired electronic structure and structural features to be considered as excellent candidates to form hybrids with and very efficient types of photodetectors.^{5–7} Device properties new synergetic behavior. To date, the properties of such can be tuned and optimized by the assembly of different molecules on the nanotubes.^{8–14} Recently, SWNTs were used to build a magnetic sensor that may potentially detect the magnetic moment of a single molecule.^{15,16} Another objective is to take advantage of the interaction via charge transfer, for example, between the assembled molecules and the nanotube to tune the transport properties of the device. This is true not only for pure organic molecules but also for paramagnetic complexes. The key point is to optimize the interaction between the assembled molecules containing the paramagnetic ion and the nanotubes without altering in an irreversible manner the electronic properties of the nanotubes. Grafting complexes through covalent bonds might introduce complexes

interacting noncovalently with carbon nanotube- based electronic systems are still to be investigated. A vanadium Schiff base complex was already covalently grafted on multiwall carbon nanotubes in order to elaborate modified electrodes with enhanced electrochemical response for reductive electro- catalysis.²² Herein we report the noncovalent assembly of the binuclear complex [Cu₂bisalophen] (noted 1 and depicted in Figure 1) on SWNTs. We demonstrate that the grafting process leads to a tuning of the CNFET device properties due to diameter-selective charge transfer between the complex and the nanotube and to the appearance of a marked tunable ambipolar behavior was chosen because its extended π system is expected to undergo strong π - π interactions with the walls of the electron-scattering centers that limit the performance and properties of the device, while noncovalent π -stacking interactions are more likely to preserve the SWNT conductance nanotubes. Synthesis of the organic ligands was already reported.²³ 1 is obtained as red crystals with an excellent yield (85%) by addition of Cu(OAc)₂ (see Supporting Information) to a solution of the organic ligand. The complex is very soluble in dichloromethane (DCM) and dichloroethane (DCE). To ensure the efficiency of the grafting process and check the integrity of the complex we used complementary and independent spectroscopy-based characterization techniques. Since those techniques can directly access molecules and carbon nanotubes characteristic transitions, which are highly sensitive to environment modifications, electron paramagnetic resonance spectroscopy (EPR), optical absorption spectroscopy, and photoluminescence spectroscopy measurements were performed on different samples.

Figure 1. Schematic view of [Cu₂bisalophen] 1.

2. RESULTS AND DISCUSSION

2.1. Preparation and Preliminary Characterization of the Cu₂/SWNT Adduct.

Pristine HiPCO SWNTs were purified using a procedure derived from that reported by Chiang et al.^{24,25} The purity of the obtained SWNT was proven among other techniques by the absence of the D band in the Raman spectra (Supporting Information). Grafting of 1 was achieved by sonication of a suspension of the purified nanotubes in a solution of dichloromethane and dimethylformamide (1:1) containing the complexes. The suspension was then filtered on a polytetrafluoroethane (PTFE) membrane and rinsed thoroughly several times with dichloromethane to remove all nongrafted complexes. A gray fine powder of the adduct (noted 1@SWNT) was obtained and further analyzed. It is important to note here that a solution of the complex without the nanotubes was submitted to the same sonication process and then analyzed with EPR and electronic spectroscopy, which ensured the integrity of the molecules. EPR spectra were recorded for 1 in a solution of CH₂Cl₂ and DMF (1:1), for the purified SWNT, and for 1@SWNT powder (Figure 2). EPR spectra of 1 correspond to what is expected for a binuclear Cu(II) complex with axial local symmetry of the Cu sites.²³ The resonance spectrum of 1@SWNT is found at the same magnetic field value (~3100 G) as for 1, indicating the presence of the binuclear complex on the nanotubes walls despite the abundant rinsing process.²⁶ This is the first evidence of the success of the noncovalent assembly of the complex on the nanotubes. The sharp band around 3340 G is attributed to the pure carbon nanotubes (Figure 2).

Figure 2. Comparison of EPR spectra of purified nanotubes (powder) (black curve), free 1 in CH₂Cl₂/DMF (1:1) solution (blue curve), and 1@SWNT (powder) obtained after filtration and extensive washing (red curve).

2.2. Electronic Spectroscopy and Photoluminescence Studies.

Along with this first characterization, an independent method used by Roquelet et al.²⁷ was used to graft 1 onto the SWNT. This method, different from the previous one, ensures the presence of isolated nanotubes in solution, which is compulsory to investigate the photoluminescence properties of the adducts. The raw HiPCo nanotubes were dispersed in a solution of pH 8 buffer plus 2 wt % sodium cholate (surfactant) using an ultrasound tip (see Supporting Information). The complex, dissolved in CH₂Cl₂, was then added to this solution and submitted again to ultrasound, leading to a biphasic system with formation of micelles in the aqueous phase. During evaporation of the organic phase, the molecular complexes insoluble in water are expected to diffuse inside the micelles, enabling their assembly on the individual SWNT coated by the surfactant and present in solution. The aqueous phase is then analyzed with electronic (UV-vis, nearinfrared) and photoluminescence spectroscopies. According to analogous measurements,^{12,14,27,28} the UV-vis spectrum of 1 is notably modified after the grafting process; the metal to ligand charge transfer (MLCT) band (450–600 nm) is red shifted by 17 nm (Figure 3), confirming the interaction between the two species. Since this shift is not observed for 1 in solution in the presence of surfactant (Figure 3top, green curve) and is not increasing for larger complex concentrations (see Supporting Information) it cannot be attributed to an interaction between the molecules and the surfactant or to molecules aggregation. Since the MLCT bands are the only ones affected, this shift may be attributed to a slight geometry modification or to a weak charge transfer process that affects the energy of the metal-centered molecular orbitals upon interaction with the nanotube. Another important feature is observed in the electronic spectra of the nanotube bands. A solvatochromic red shift attributed to coating of the nanotube by the molecules can also be seen for the SWNT (n,m)-type absorption bands between 900 and 1200 nm (Figure 3, bottom), confirming their interaction with 1. The impact of the molecules on the nanotube absorption properties is expected to be smaller than that of a nanotube on the molecules' properties since the SWNTs are mesoscopic objects and can alter several complexes at a time. The red shift is therefore weaker and ranges from 0 to 5 nm. From the absorption spectra this shift does not seem to occur for all (n,m) types of nanotubes. We have thus investigated the nanotubes dispersion photoluminescence spectra. The results confirmed the red shift for only some (n,m) nanotube types (Figure 4). Using maps of photoluminescence excitation (PLE), which gave us the relative ratio of the (n,m) types of SWNT and an experimental Kataura plot,²⁹ we attributed each emission band of the photoluminescence spectrum (Figure 4) to a (n,m) type. The attribution is made for the most abundant type even though the band attributed to (7,6) contains a contribution from the (9,4) and (8,4) types as well. The most affected type of nanotube within the range of excitation of 532 nm is the (7,6) one ($\lambda_{11} = 1130$ nm). This band undergoes a shift of 5 nm upon assembly of 1 without a decrease of its intensity. While the (8,1)-type band has a shift of 3.5 nm, the (10,2) type band of 2 nm and the (8,6) type band are not shifted at all; the intensity of these latter bands decreases slightly. These modifications are attributed to a diameter-selective charge transfer, particularly for the (7,6)-type band, where only a shift is observed and no intensity decrease. Diameter selection cannot be excluded since the intensity of some types (the smallest) decreases without an energy shift.

Figure 3. (Top) UV-vis spectra of 1 (black curve, MLCT bands between 400 and 600 nm), 1 in pH 8 buffer with 2 wt % sodium cholate (green curve), raw HiPCO SWNT in pH 8 buffer with 2 wt % sodium cholate (blue curve), and 1 with SWNT in pH 8 buffer with 2 wt % sodium cholate after evaporation of CH_2Cl_2 (red curve). (Bottom) Near-infrared spectra obtained with the same samples of raw HiPCO SWNT in pH 8 buffer with 2 wt % sodium cholate (blue curve) and 1 with SWNT in pH 8 buffer with 2 wt % sodium cholate after evaporation of CH_2Cl_2 (red curve).

Figure 4. (Top) Photoluminescence spectra of raw SWNT (black curve) and 1@SWNT both in pH 8 buffer with 2 wt % sodium cholate and CH_2Cl_2 . (Bottom) Zoom on the (7,6) band.

2.3. Theoretical Calculations.

In order to rationalize the molecule–nanotube interaction effects theoretical density functional calculations (DFT) were performed with the Siesta code^{30,31} (see Supporting Information) for the (n,m) nanotube type that seems to be the most affected during the grafting process: the (7,6). The more stable optimized geometry has a perpendicular orientation as shown in Figure 5. Time-dependent DFT calculations based on this optimized structure were then performed to determine the vertical excitations of **1**₃₂ before and after grafting.³³ Without solvent the calculated excitations were found at 487 and 523 nm for **1**, which is in fair agreement with the experimental values (494 and 528 nm, respectively). For **1**@SWNT, the calculations show a shift of the two bands to 520 and 568 nm for the interacting molecule to be compared to the experimental values of 507 and 547 nm. Even though the calculations do not reproduce exactly the values of the absorption band energies, they reproduce the experimental red shift trend and confirm the origin of the change in energy of the absorption bands as being due to the interaction between the binuclear Cu₂ complex and the nanotubes.

Figure 5. View of the optimized structure (perpendicular orientation for **1** grafted onto a (7,6) nanotube from theoretical calculations). Blue, red, light blue, and brown spheres correspond to copper, oxygen, nitrogen, and carbon atoms, respectively, and hydrogen atoms are indicated as brown sticks.

2.4. Transport Studies.

The studies performed above demonstrate two important features: first, the binuclear complex adheres well onto the nanotubes as evidenced by EPR and, second, there is an electronic interaction between the paramagnetic complexes and the nanotubes as evidenced by the electronic and photoluminescence spectra and confirmed by theoretical calculations. In addition to this electronic interaction one may expect the presence of a charge transfer between the molecules and the nanotubes. Even though some techniques like Raman are suitable to study the charge transfer, investigation of the transport behavior may give more complete information about the electronic interaction occurring between the nanotubes and **1** and evidence other electronic phenomena, such as gate-dependent ones, not possible to account for otherwise. The transport studies were carried out using a CNFET device in ambient air. The device was obtained following a new strategy based on self-assembled monolayers (SAMs), which has been described (see Supporting Information).³⁴ Since the interaction was proved between **1** and HiPCO SWNT, the grafting results were thought to be identical or close to those existing with the HFCVD nanotubes used in these devices. The characteristics of the FET device were first investigated. Current (I_d) versus gate voltage (V_g) curves show a p-type FET behavior (ON state at $V_g < 0$) and no ambipolar effect, as often found for silica CNFET in ambient air,^{35–37} with a very good I_{ON}/I_{OFF} ratio of four decades. Indeed, the ambipolar behavior is usually only observed when oxygen and water are removed by pumping, thus restoring the expected properties of the nanotubes that are intrinsic semiconductors. Hysteresis is observed as a result of charge injection from the CNT to the nearby region (Figure 6).³⁸

Figure 6. I_{ds} vs V_g curves for a CNFET device before (black curve) and after grafting of **1** and rinsing with DCE process. Experimental starting gate potential is -20 V, and current evolution with V_g is given by the blue arrows.

The hybrids were then produced by evaporation of a $5 \mu\text{L}$ drop of a solution of **1** in DCE deposited on the CNFET surface followed by a thorough DCE washing process of the device to remove any nongrafted molecules. I_{ds} vs V_g measurements were then performed. The subthreshold swing $S_w = [dV_g/d \log(I)]$ (green slopes in Figure 6) remains unchanged upon grafting, indicating that treatment leaves the gate unaffected. However, the I_{ON} current decreases, implying that the complexes are interacting with the electron flow, producing scattering centers.¹ While no appreciable variation is observed after repeated treatment of the FET with DCE alone (see Supporting Information), drastic changes can be observed on the I_{ds} vs V_g hysteresis curves after the grafting operation (Figure 6). The ON/OFF threshold voltage V_{th1} decreases from -5 to -8 V as **1** interacts with the nanotubes sidewalls, and an ambipolar characteristic appears for high V_g values. These changes are attributed to charge trapping as well as charge transfer from the complexes to the SWNTs (V_{th1} decreases),³⁹ evidencing a n-type doping on the nanotube, that is, a transfer of negative charges. For this gate sweep the device is first in the p-type ON state. Then holes in the nanotube vicinity are detrapping while the gate is swept toward positive values, until the OFF state is reached. Finally, enhanced by the grafting of **1** onto the SWNT, electrons start to be trapped in the nanotube vicinity while the device is slowly reaching its n-type ON state. This experiment is definitive proof of the occurrence of an electronic density transfer from the paramagnetic complexes to the SWNTs. In order to get a better understanding of the origin of the Cu₂ complex/nanotube interaction, especially the phenomenon responsible for the ambipolar behavior, several deposition washing cycles were performed (Figure 7, top).

Figure 7. (Top) I_{ds} vs V_g curves for a CNFET device before (black curve) and after a different number of grafting–rinsing cycles with **1**. Experimental starting gate potential is -20 V, and evolution of the current is given by the black arrows on the black curve. (Bottom left) Electrons transfer from the complexes HOMO to the p-type SWNTs valence band. (Bottom right) As V_{Gate} becomes positive, the bands

are bending toward lower energies, allowing electron transfer from the HOMO of the complexes to the conduction band of the SWNTs. CNFET thus becomes n-type for positive V_{Gate} values, leading to an ambipolar characteristic.

As the number of cycles increases, V_{th1} decreases and the ambipolar effect becomes more and more pronounced. While the increased shift of the hysteresis curve can be attributed to increasing electron transfer from the complexes to the SWNTs as more and more molecules are grafted onto their sidewalls, the origin of the change in the magnitude of the ambipolar effect is not straightforward. As various external factors can affect the I_{ds} vs V_{g} characteristic, several aspects must be checked to ensure that the more pronounced ambipolar phenomena is indeed related to the increase of the molecules' concentrations on the nanotube and not to other effects. Since the subthreshold swing is not affected by the grafting and since the rinsing process removes all nongrafted and

substrate-deposited molecules one can safely assume that the observed effects are not due to the molecules perturbing the environment of the nanotubes conducting channels. Moreover, since repeated treatments by DCE alone have no effect on the I_{ds} vs V_{g} characteristic (see Supporting Information) and since the n-type subthreshold (positive slope in Figure 7, top) swing increases with the number of cycles, the ambipolar effect cannot be due to external effects but only to the noncovalent interaction between the molecules and the nanotubes. To understand the intrinsic character of the ambipolar effect one needs to consider Figure 7 (bottom). As V_{Gate} becomes positive, the conduction band of the nanotubes is bending toward lower energies, thus being able to receive electrons from the HOMO of the molecules. The electrons then become the main charge carriers, leading to an n-type behavior. This interpretation is supported by the fact that the intersection of the two pink slopes (Figure 7bottom), indicative of the potential for which the conduction type starts to change, occurs around the same $V_{\text{Gate}} \approx -10$ V value for both the third and the eighth cycle. However, we do not exclude the fact that this effect is also due in part to a global shift of the characteristic due to the existing charge transfer process.³⁷ This reproducible, easy to generate, and tunable ambipolar character is of major interest since most logic circuits need to integrate both n- and p-type conductors, and the presence of both kinds of charge carriers can lead to exciton recombination and thus photo- luminescence phenomena.

4. CONCLUSION

We have thus demonstrated that the Cu₂bisalophen complexes can be assembled in a noncovalent manner on SWNTs elaborated by HiPCO and hot filament-assisted chemical vapor deposition techniques. The origin of the nanotubes seems to not affect the electronic interaction responsible for this assembly. However, electron transfer from the molecules to the nanotubes is only evidenced with the transport studies. Noncovalent grafting of metal transition complexes onto SWNTs in a CNFET channel leads to electron transfer from the molecules to the nanotube and generates a tunable ambipolar effect in ambient air conditions. This opens the possibility to design new kinds of nanohybrid circuits. Beyond this important result, new kinds of CMOS inverters or logic circuits may be realized as well as new powerful photocurrent devices by combining the evergrowing number of optic properties of inorganic complexes with promising optoelec- tronic ones of SWNTs. Furthermore, the mere presence of an electronic interaction between the conducting electrons of the nanotubes and the localized electrons of the paramagnetic complex may be used to tune the exchange coupling interaction of the binuclear paramagnetic species. In addition, a diameter- selective charge transfer between the complex and the nanotubes seems to occur, which will be the subject of further investigations. Schiff base binuclear complexes are particularly appealing since they are relatively easy to prepare. More importantly, they are very stable in solution, which is a requirement for elaboration of the modified CNFET. Their electronic and magnetic properties may be tuned by changing the nature of the metal ions and modifying the organic ligand itself adding donor or acceptor groups. Thus, they offer an attractive playground for tuning the electronic behavior of CNFET devices.

* Supporting Information

Synthetic procedure and full characterization of the Cu₂ complex, procedure for purification of the nanotubes, spectra of the hybrids, procedure for fabrication and characterization of the CNFET, and methods used for DFT calculations. This material is available free of charge via the Internet at <http://pubs.acs.org>.
