Supporting Information

ABSTRACT: The adsorption behavior of the amino acid glycine in mesoporous silica has been investigated using a combination of quantum chemical calculations and NMR spectroscopy experiments. Glycine adsorption on two representative sites of an amorphous silica surface, vicinal silanols and a silanol nest, was investigated by DFT-D. The effect of water coadsorption on the energetics of adsorption and NMR shifts was characterized. It was found that the silanol nest is a more favorable site for glycine adsorption due to a local increased H-bond density. Co-adsorption with water is also favored, especially a water molecule between a SiOH and the ammonium moiety. NMR chemical shifts computed on these models fall into the observed ¹³C and ¹⁵N experimental range, suggesting that the presence of different energetically comparable adsorption configurations cannot be excluded.

1. INTRODUCTION

An increased interest has been shown in the past for the synthesis of templated inorganic materials due to their potential applications in catalysis and controlled release.^{1,2} These applications are closely related to the binding of biomolecules on inorganic surfaces, but questions related to the nature of interfacial interactions still need to be addressed. Studies on simple model systems are thus needed for a thorough understanding of more complex systems. This is the reason why building block approaches are developed by some groups in order to understand the adsorption of biomolecules (from amino acids to proteins) on solid surfaces.³ To this respect, glycine, the smallest and simplest amino acid, simultaneously exhibits both carboxylate/carboxylic and amine/ammonium moieties and, thus, represents a good reference object for other more complex biological molecules. Indeed, a number of papers appeared in recent years concerning the adsorption of glycine or other amino acids on oxide surfaces,⁴ and a review specially devoted to amino acids on silica has recently been published.¹³

Recent developments in solid-state NMR open promising perspectives for the detailed characterization of such interactions between small molecules and inorganic surfaces.⁶ This local spectroscopic technique can establish “dialogues” between nuclear spins. In that sense, solid-state NMR is a perfect tool of investigation for the hybrid organic–inorganic

interfaces in nanomaterials. NMR spectroscopy and more particularly dipolar recoupling experiments were used recently to identify interacting moieties in alanine adsorbed on a mesoporous silica SBA-15 surface,⁷ and later in glycine adsorbed on the same support.⁸ In both cases, the authors show that the ammonium group interacts directly with silanols (predominantly terminal ones) on the surface while the carboxylates seem to freely reorient.

There has been a continuous increase in the number of ab initio theoretical studies on the adsorption of amino acids or organic molecules on several oxide surfaces such as amorphous or crystalline silica,^{9–13} alumina,¹⁴ ZnO,^{15,16} Cr₂O₃,^{17,18} TiO₂,^{19–25} and hydroxyapatite.^{5,26–29} Even glycine, the simplest amino acid, may present different adsorption mechanisms on an oxide surface: first, it may be adsorbed in neutral, cationic, zwitterionic, or anionic forms according to the protonation state of the amine and carboxylate groups (NH₂–CH₂–COOH, NH₃⁺–CH₂–COOH, NH₃⁺–CH₂–COO[–], NH₂–CH₂–COO[–], respectively). Second, adsorption may be driven by covalent bonding, H-bonding with the surface, ionic

interactions, self-assembly between the biomolecules, and any combination of those possibilities.⁴

Most of the ab initio studies of glycine adsorption were performed in the absence of solvent; that is, they are relevant to adsorption from the gas phase. However, the presence of solvent molecules (e.g., water) may significantly influence glycine adsorption equilibria and kinetics. On the one hand, the solvation of the biomolecule may hinder its interaction with the surface. On the other hand, the coadsorption of water and biomolecule may actually contribute to stabilizing the adsorbed form. Water may also lower the kinetic barriers for conformational changes or proton transfers. Only few ab initio studies of the adsorption of amino acids on surfaces in the presence of water as a solvent have been undertaken, due to the extensive cost of ab initio molecular dynamics (MD) calculations and of the very short time periods simulated during a calculation (a few picoseconds). Marx and co-workers studied the adsorption of glycine on pyrite at the solid–liquid interface.^{30–33} In this series of studies, glycine was found to be preferentially solvated in the liquid phase and not adsorbed on the ideal surface of pyrite, while the presence of sulfur vacancies caused a specific adsorption involving coordination of the carboxylate to iron ions, with or without coadsorption of water. On rutile TiO₂, Langel and Menken²³ investigated the adsorption of glycine, methionine, cysteine and serine. MD simulation revealed that the most stable adsorbed form of the amino acids involved coordination of the carboxylate moiety to two Ti⁴⁺ centers, in a bridging position (in addition, cysteine could also coordinate through its deprotonated thiol group and thus behave as a bidentate ligand). An adsorption mechanism involving carboxylate coordination to Ti⁴⁺ was also found to be operating for glycine (Gly) on rutile (110).³⁴ We have recently explored the adsorption mechanism of glycine on Boehmite (AlOOH).³⁵ Inner-sphere adsorption (by unidentate carboxylate coordination to Al³⁺) was favored over outer-sphere, with adsorption energies of –160 and –20 kJ·mol^{–1}, respectively.

On silica, in contrast, the favored amino acid adsorption mechanisms do not involve coordination, or covalent bond formation. Recently, Nonella and Seeger³⁶ investigated the alanine–silica interaction in the presence of bulk water by means of DFT-MD. They found that the strongest interaction occurred for a positively charged alanine ion and a negatively charged silica surface. The formation of H-bonds with isolated silanols on Gly/SiO₂ systems was found to be weakly exothermic,^{9,11} whereas the formation of a H-bond network with a specific silanol nest could induce strong bonds of glycine with the surface.¹⁰ “Microsolvating” water molecules were added to the system to understand the effect of water coadsorption. Several first principles molecular dynamics runs indicated that in the dominant conformation the COO[–] moiety is directly H-bonded to one geminal SiOH group on the surface, whereas NH₃⁺ interacts with water molecules far from the surface.¹⁰ Zhao et al.³⁷ and Walsh et al.³⁸ obtained very similar results: the dominant configuration exhibits the COO[–] group pointing toward the surface in direct contact with geminal SiOH groups, while the NH₃⁺ prefers to interact with bulk water, away from the surface. Interesting data concerning the effect of increasing numbers of microsolvating water molecules on the structure of glycine interacting with an edingtonite SiO₂ surface can also be found in the work of Rimola et al.³⁹

The ideal way to thoroughly understand adsorption at the solid liquid interface, however, is to couple the experimental

and the theoretical approaches by performing an ab initio assisted interpretation of spectroscopic data. For instance, the spectroscopic data obtained by NMR and the theoretical structural models of glycine adsorption can be associated by performing first principles calculations of the NMR parameters, starting from structural models based on DFT. For that purpose, the GIPAW (Gauge Included Projected Augmented Wave) method, first proposed by Pickard and Mauri,⁴⁰ is now considered as a tool of choice for solid state NMR calculations (in the frame of DFT and under periodic boundary conditions).⁴¹ The combined theoretical/experimental approach^{42,43} and in particular the DFT structural modeling/solid state NMR/GIPAW approach represents a very useful tool for the detailed characterization of organic–inorganic interfaces⁴⁴ and seems therefore adequate for a detailed study of the glycine–silica interface at an atomic level.

In this contribution, a mesoporous MCM-41 silica^{45,46} was prepared and loaded with glycine. Solid-state NMR was then used for the investigation of the adsorbed amino acid and in particular for investigating the proximities between silanols, water molecules and glycine molecules using two-dimensional ¹H–X HETCOR CP MAS experiments (X = ¹³C, ¹⁵N, and ²⁹Si). The amorphous silica slab model we previously developed⁴⁷ was used to study various configurations of glycine adsorption, taking explicitly into account possible interfacial water molecules. Finally, and in order to determine the relevance of the models, first principles calculations of NMR parameters were performed by using the GIPAW method for all involved nuclei and compared with experimental data.

2. EXPERIMENTAL DETAILS

2.1. Material Preparation. **2.1.1. MCM-41 Sample Synthesis.** Mesoporous silica MCM-41 was obtained by solubilizing cetyltrimethylammonium bromide (CTAB, 17.24 g) in H₂O (350 g) at 40 °C and mixing this solution with an aqueous solution of 52.5 g of sodium silicate (27% SiO₂, 10% NaOH) in 54.5 g of water for 10 min. The SiO₂/CTAB/NaOH/H₂O molar ratio was 1:0.55:0.25:127. The pH was then adjusted to 8.5 by adding, under stirring, ~108 mL of 1 M HCl. The mixture was heated at 90 °C for 24 h. A solid white powder formed in the reaction mixture; it was washed with distilled water, dried at 60 °C overnight, and then heated at 540 °C for 8 h under air flux to remove the surfactant.

2.1.2. Gly Deposition on MCM-41. The calcined MCM-41 sample was loaded with glycine according to the “incipient wetness” procedure: 0.300 g of MCM-41 was impregnated with a small amount (2 mL) of 0.1 M aqueous glycine solution, allowing the complete filling of the pore volume of MCM-41 (without formation of a bulk liquid phase). This resulted in the deposition of 0.67 mmol Gly per gram of MCM-41, or a loading of 5.0 wt %. The sample was then dried at 60 °C for 3.5 days. In order to increase the signal-to-noise ratio of the NMR spectra, glycine isotopically enriched in ¹⁵N and ¹³C (the latter on the carboxyl function) was employed. This sample will be called Gly/MCM.

Nitrogen adsorption/desorption isotherms were recorded at 77 K with a Micromeritics ASAP2000 apparatus, after degassing under vacuum (1 × 10^{–3} Torr) at 250 °C for pure calcined MCM-41 or 40 °C for the glycine-loaded sample.

2.2. Solid-State NMR Experiments. The ¹³C, ¹⁵N CP (Cross-Polarization) MAS experiments were recorded on a Bruker Avance 400 spectrometer (9.4 T, $\nu_0(^1\text{H}) = 400.78$ MHz,

$\nu_0(^{13}\text{C}) = 100.61$ MHz, $\nu_0(^{15}\text{N}) = 40.56$ MHz), and 2D HETCOR (HETeronuclear CORrelation) experiments were recorded on a Bruker Avance III 300 spectrometer (7.0 T, $\nu_0(^1\text{H}) = 300.29$ MHz, $\nu_0(^{13}\text{C}) = 75.51$ MHz, $\nu_0(^{15}\text{N}) = 30.44$ MHz, $\nu_0(^{29}\text{Si}) = 59.66$ MHz). At both fields, Bruker 4 mm double resonance MAS probes were used, and the samples were spun at the magic angle at 14 kHz.

2D ^1H -X HETCOR CP MAS experiments (X = ^{13}C , ^{15}N , and ^{29}Si) were recorded with ramped-amplitude cross-polarization (RAMP-CP)⁴⁸ in the ^1H channel to transfer magnetization from ^1H to X (typically, 64 increments of 63 μs were used with 600 scans per acquisition). The ^1H field was ramped from 50 to 100% while the X RF field was set around 65 kHz. RD = 3 s, $t_{90}(^1\text{H}) = 3$ μs , CP contact time = 1 ms, optimized ^1H spin-64 decoupling.

A single pulse ^{29}Si NMR MAS spectrum was also recorded at 7.0 T with a Bruker 7 mm double resonance MAS probe, spinning at 5 kHz, 5.0 μs $\pi/2$ pulses, and a recycle delay of 60 s. Spectra deconvolutions were performed using the Dmfit software.⁴⁹ ^1H , ^{13}C , and ^{29}Si chemical shifts were referenced to external TMS, while ^{15}N was referenced to external CH_3NO_2 .

2.3. Computational Details. **2.3.1. Ab Initio Geometrical Configurations and Molecular Dynamics Calculations.** All calculations were performed using the ab initio plane-wave pseudopotential approach as implemented in the VASP code.^{50,51} The Perdew–Burke–Ernzerhof (PBE) functional^{52,53} was chosen to perform the periodic DFT calculations with an accuracy on the overall convergence tested elsewhere.^{47,54–58} The valence electrons were treated explicitly and their interactions with the ionic cores are described by the Projector Augmented-Wave (PAW) method,^{59,60} which allows one to use a low energy cutoff equal to 400 eV for the plane-wave basis. The integration over the Brillouin zone was performed on the Γ -point, in all calculations.

The potential energy surfaces (PESs) were systematically explored by ab initio molecular dynamics at 300 K, starting from several configurations. The time step was set at 1.5 fs; several starting conformations were considered (but no statistic was performed on the starting conformations), and the run was stopped when an average stable conformation was reached during 500 fs or more; we used a microcanonical ensemble in the NVE (constant number of molecules, constant volume and constant energy) approach. To avoid fluctuations due to the large time step chosen, the mass of the hydrogen atom was set to 3. The local minima found in the PES were then optimized at 0 K. It is noticeable that this MD approach allowed us to find the minima of the PES showed in the present paper, which were not intuited beforehand. Glycine was adsorbed in its zwitterionic form (ZG).

In the geometry optimizations at 0 K, the positions of all atoms in the supercell are relaxed in the potential energy determined by the full quantum mechanical electronic structure until the total energy differences between the loops is less than 10^{-4} eV. In a second step, the DFT-D approach⁶¹ was applied as implemented in VASP, which consists in adding a semiempirical dispersion potential to the conventional Kohn–Sham DFT energy. In particular we used the DFT-D method of Grimme⁶² up to D2 correction.

The energies of interaction/adsorption of glycine on the surface were calculated following different reactions: First, neutral glycine (NG) was considered as the adsorbant. The adsorption energy ΔE_{ads} was calculated as follows:

$$\Delta E_{\text{ads}} = E(\text{G, Sil}) - E(\text{NG}) - E(\text{Sil}) - nE(\text{H}_2\text{O}) \quad (1)$$

where $E(\text{NG})$, $E(\text{Sil})$, and $E(\text{H}_2\text{O})$ are the total electronic energies of NG, silica surface, and one water molecule obtained after separate geometry optimization. $E(\text{G, Sil})$ is the energy of the optimized (glycine + silica + n water) system with glycine adsorbed on the silica surface. The number of water molecules in the models runs up to 3.

The adsorption energy can be decomposed into interaction and deformation energies, as follows:

$$\Delta E_{\text{ads}} = \Delta E_{\text{binding}} - \Delta E_{\text{deform-mol}} - \Delta E_{\text{deform-surface}} \quad (2)$$

where $\Delta E_{\text{deform-mol}}$ of the molecule and $\Delta E_{\text{deform-surface}}$ of the surface indicates the energy required for the molecule (respectively, the surface) to adapt to the constraints induced by the surface (respectively, the molecule), and $\Delta E_{\text{binding}}$ is the energy of the bond between the surface and the molecule, in the geometries of the adsorption configuration. ΔE_{ads} is negative, indicating an exothermic process, when the binding energy between the molecule and the surface is more important than the induced respective deformations.

2.3.2. Ab initio Calculations of NMR Parameters. The first principles NMR calculations were performed within Kohn–Sham DFT using the QUANTUM-ESPRESSO software (available online).⁶³ The PBE generalized gradient approximation^{52,53} was used, and the valence electrons were described by norm conserving pseudopotentials⁶⁴ in the Kleinman–Bylander⁶⁵ form. The core definition for O, C, and N is $1s^2$ and $1s^2 2s^2 2p^6$ for Si. The core radii are 1.2 au for H, 1.5 au for O, 1.6 au for C, 1.45 au for N, and 2.0 au for Si. The wave functions were expanded on a plane wave basis set with a kinetic energy cutoff of 1088 eV. The integral over the first Brillouin zone was performed using a Monkhorst-Pack $1 \times 1 \times 1$ k-point grid for the charge density and chemical shift tensor calculation. The shielding tensor is computed using the GIPAW⁴⁰ approach which permits the reproduction of the results of a fully converged all-electron calculation. The isotropic chemical shift δ_{iso} is defined as $\delta_{\text{iso}} = -[\sigma - \sigma^{\text{ref}}]$, where σ is the isotropic shielding and σ^{ref} is the isotropic shielding of the same nucleus in a reference system as previously described.^{66,67}

2.3.3. Description of the Model. The adsorption of glycine was studied using a silica model structure described and characterized in a previous work.⁴⁷ In summary, the model consists of a $\text{Si}_{27}\text{O}_{54}$ slab hydrated with 13 H_2O molecules. The silanol density at the surface is 5.8 nm^{-2} , and unit cell dimensions are $12.77 \times 17.64 \times 25.17 \text{ \AA}^3$. The slab has a density of approximately 1.7 g/cm^3 . The number of Si atoms belonging to tetrahedra exposed on the surface is approximately 8 nm^{-2} . The same slab has been used in studies in which the model was used to describe a catalyst support.^{68–71} Despite the fact that the global silanol density is higher than the one usually reported for MCM-41,⁷² locally, the different expected types (terminal and geminal) are present on the model surface, enabling, thus, a correct, local, description of the interaction sites.

3. RESULTS AND DISCUSSION

3.1. Surface Area and Porosity. Nitrogen adsorption/desorption isotherms of the calcined MCM-41 and the glycine-loaded sample (see the Supporting Information for details, Figure S1 and Table S1) provided specific surface areas, evaluated by BET calculations,⁷³ of 1060 and $830 \text{ m}^2 \cdot \text{g}^{-1}$,

respectively. Both the mean pore diameter estimated by the BJH method⁷⁴ and the mesoporous volume decrease after loading, in line with the successful incorporation of glycine in the mesopores of MCM-41.

3.2. Solid-State NMR Investigation. In the carboxylate region, the ^{13}C CP MAS spectrum of glycine encapsulated in mesoporous silica (Figure 1) exhibits a sharp signal at 176.4 ppm and a distribution of broader ones ranging from 168 to 175 ppm, with one maximum at 173.6 ppm. Similar results have already been observed for glycine adsorbed on nonporous silica nanoparticles (Aerosil 380):^{8,75} the sharp line was assigned to bulk α -glycine⁷⁶ (^{13}C CP MAS spectra of the α , β and γ polymorphs of glycine are presented in Figure 1), while the broader line could correspond to a population of glycine molecules interacting with silica surface groups (most likely silanols) and/or adsorbed water molecules. A ^{13}C single-pulse (SP) MAS NMR spectrum of the sample was also recorded (Supporting Information Figure S2): this experiment corresponds to direct ^{13}C detection, *without CP* from ^1H to ^{13}C . The signal assigned to crystalline glycine is very similar in the two spectra (SP and CP), but important differences are visible in the 168–175 ppm range. Instead of a distribution of broad signals in the CP spectrum, only one sharper signal at 173.5 ppm is present in the SP spectrum, with no clear sign of any of the broader components present in the CP spectrum. This suggests the existence of two populations of glycine molecules: one mobile enough not to be detected by CP due to an efficient averaging of the ^1H – ^{13}C dipolar interactions, and one more rigid detected by CP, *a priori* corresponding to the molecules strongly interacting with the surface (apart from crystalline forms of glycine). Similar observations were already reported for encapsulated molecules in MCM-41.^{6,77} The population detected by CP is thus the one of interest for the present study.

A two-dimensional ^1H – ^{13}C HETCOR CP MAS NMR experiment was recorded in order to discriminate between ^1H sites according to their proximities to the different carbon atoms (Figure 2a). The ^{13}C signal at 176.4 ppm assigned to bulk α -glycine clearly shows two cross peaks with proton signals at 3.2 ppm and 8.4 ppm corresponding to the methylene group bonded to the carboxylate and to the ammonium group in interaction with the carboxylate of a neighboring molecule through NH – OOC hydrogen bonds in the bulk state. Two cross peaks centered at 4.3 and 7.2 ppm are observed for the ^{13}C signal at 173.6 ppm. The first ^1H chemical shift is possibly due to the superposition of methylene and water signals while the second is consistent with an ammonium group or with silanols/water in interaction with the carboxylate. Finally, the larger ^{13}C signal centered at 171.5 ppm only correlates with a proton signal at 4.7 ppm. The latter is usually assigned to the protons of silanols in fast exchange with adsorbed water on imperfectly dehydrated silica, be it mesoporous or nonporous.⁷⁸ The conventional ^1H MAS spectrum (Supporting Information Figure S3) shows indeed a predominant large signal centered at 5 ppm characteristic of the presence of water.

The ^{15}N CP MAS spectrum of Gly/MCM (Figure 3) shows a narrow signal at –346.6 ppm corresponding to the chemical shift of ammonium groups in α -glycine and a second component centered at –348.5 ppm most probably corresponding to the glycine in interaction with the surface. A two-dimensional ^1H – ^{15}N HETCOR CP MAS NMR experiment was then recorded to identify ^1H chemical shifts of the ammonium groups of these two types of glycine (Figure 2b). Consistently with the ^{13}C results, the ^{15}N signal at –346.6 ppm shows a proton cross peak at 8.6 ppm, assigned to the ammonium protons of bulk glycine⁷⁶ while the ^{15}N peak at

–346.6 ppm is correlated to a ^1H signal at 6.4 ppm possibly corresponding to –NH protons involved in a H-bond network with the silica surface. The weak cross peak at 3.7 ppm can be assigned to the protons of the CH_2 linked to the ammonium.

Finally, the 2D ^1H – ^{29}Si HETCOR CP MAS NMR spectrum of the sample (Figure 2c) confirms that the protons with chemical shift values centered at about 5 ppm are strongly correlated with surface silicon atoms (they were assigned above to silanols in fast exchange with water). Overall, the HETCOR results are very similar to those published by Ben Shir et al. for Gly/SBA-15 in the “intermediate” hydration state.⁸

3.3. Theoretical Investigations of Adsorption Geometries. Several combinations of H-bonds between glycine and the surface were investigated. We refer to our previous paper for the description of the model silica surface,⁴⁷ which exhibits vicinal and geminal silanols and their combinations into silanol nests. Using this model, we explore the possibility of cooperative H-bond formation between glycine, silanols, and water.

First, glycine interaction with two types of surface sites (vicinal, and silanol nest containing geminal silanol groups) was investigated. Then water was coadsorbed with glycine. The adsorption energies were calculated using eq 1.

Zwitterionic glycine (ZG) adsorption through one or two H-bonds with the silanols results in spontaneous neutralization to neutral glycine (NG), yielding adsorption energies of –55 and –62 kJ/mol (Figure 4a and b). It must be underlined that, in

this configuration, the surface does not “solvate” the glycine molecule, in the sense that the interaction is not sufficient to stabilize the zwitterionic form with respect to the neutral form as happens, for example, in water, in conformity with previously calculated results.^{9,11} When glycine is allowed to make three H-bonds to the surface (Figure 4c,d), the ZG form is stabilized, although the energy of adsorption (–64 and –69 kJ/mol) is not significantly more negative than in the previous case. The rather weak interaction of glycine with vicinal silanols was confirmed with MD runs at 300 K. For all the previous structures, the glycine molecule spontaneously desorbs from the surface in its neutral form.

The same trend of neutralization was observed on the geminal silanol pair with glycine forming two H-bonds, with an energy of adsorption of –64 kJ/mol (Figure 5a). The geminal pair behaves similarly to the vicinal silanols, in agreement with previous results regarding water adsorption on silanols.⁴⁷ These results suggest that geminal silanols do not exhibit an increased acidity as compared to vicinal ones. Then, a minimum in the potential energy surface (glycine/silanol nest) was searched by means of molecular dynamics followed by geometry optimization. Figure 5b shows the most stable configuration obtained, with three H-bonds formed. The COO moiety is two times H-bond receiver from the geminal pair; in addition, the NH_3 moiety is one time H-bond donor to a vicinal silanol. Subsequently, the ZG form was stabilized and an adsorption energy of –111 kJ/mol was calculated, exhibiting a more exothermic adsorption than on vicinal silanols.

The most stable configuration in dehydrated conditions, (Figure 5b), shows the glycine molecule parallel to the surface with three H-bonds, an additional bond being formed between the NH_3^+ moiety and a vicinal silanol. Moreover, a $\text{Si-O-H-O-C-O-H-O-Si-O}$ cycle is formed. The energy of glycine adsorption is now –111 kJ/mol (148 kJ/mol vdW corrected). This energy of adsorption is much more exothermic than that calculated in other configurations. To better understand this result, the adsorption energy was decomposed into interaction and deformation energies as in eq 2.

Table 1 reports those energies for the most stable configurations obtained for glycine adsorbed on vicinal silanols and on a silanol nest. The H-bond network of silica has slightly changed in the presence of adsorbed glycine, with reorientations of H-bonds. The average deformation energy of the silica model is rather weak (38.5 ± 1 kJ/mol), which is not surprising since this solid is known to be very flexible. The average deformation energy of the glycine molecule is 68 ± 5 kJ/mol. Thus, deformation energies do not vary significantly between both configurations, and they cannot explain the differences in adsorption energies. It should be noted that the energy trends in Table 1 are not altered after inclusion of dispersion forces in a same set of model systems (i.e., the same number of atoms), as all energies are uniformly increased by about 30–50 kJ/mol depending on the degree of hydration. This correction is similar for both types of silanols, i.e. geminal and terminal. The most favorable adsorption configuration is found on geminal silanols, confirming our former result.¹⁰

We performed the following additional calculations: for the most stable configurations obtained in each case (vicinal silanols/silanol nest), the atoms of glycine and the oxygens surrounding it were kept frozen. The other atoms of the structure were eliminated. Oxygen atoms were saturated with H atoms to form water molecules; those H atoms were optimized, converging into the structures shown in Figure 6. It was noticed that the interaction of glycine with the water clusters increases with the size and H-bond connectivity in the water cluster, from –53 to –114 kJ/mol. Indeed, water molecules help to screen the glycine dipole, and thus to stabilize the negative and positive charges of zwitterionic glycine. In other words, the high local silanol density, rather than the nature of the silanols, explains the increased (i.e., more negative) adsorption energy of glycine on silica. Such an increased reactivity of silanol nests was observed on other models (molecular and peri-

odic).^{57,68–71,79,80}

In order to obtain a benchmark for the experimental NMR analysis showing the presence of a non-negligible amount of water, water molecules bridging glycine and the surface were considered, to calculate the corresponding NMR shifts (vide infra). This was achieved by adding three water molecules to the model system. Figure 7 shows the two most stable configurations obtained after MD followed by geometry optimization of the local minima. In both the silanol nest and vicinal silanol cases, the water molecules bridging the COO[–] moiety to the silanols are H-bond donors to COO[–] and H-bond acceptors from silanols. In contrast, water H-bond acceptors from NH₃⁺ are H-bond donor to silanols/siloxane oxygens. The energies of glycine+water coadsorption are –253 (–305) and –193 (–233) kJ/mol for silanol nest and vicinal silanols respectively, at the DFT (DFT-D) level. Again, we notice that the inclusion of van der Waals forces enhances the adsorption energy, by about 45 kJ/mol.

When only one water molecule is added to the model system as is the case in the last configuration, the glycine is found to interact directly with silanol groups through the carboxylate group whereas the ammonium group interacts via the water molecule. The adsorption energy obtained is –168 (–219) kJ/mol (See Figure 8). We notice that the addition of one water molecule to the NH₃⁺ end is exothermic by –72 kJ/mol. Adding water molecules at the COO[–] end is exothermic by –43 kJ/mol per water molecule. Those values fall to –60 (one water molecule) and –31 (two more water molecules) kJ/mol, respectively, considering the ZPE differences between the gas phase water and water adsorbed on the surface.⁸¹ It seems thus that the addition of one water molecule at the ammonium end is more exothermic than at the carboxylate end. This may be due to the better screening of the charge of the proton in NH₃⁺ by an additional water molecule. Such a trend was already

observed in a previous work.¹⁰ Moreover, it was recently shown by molecular dynamics studies that the NH_3^+ moiety does not interact directly with the surface silanols, whereas the carboxylate end does, at the silica-water interface.^{37,82}

The results present a first order approximation for systems considering a real silica-water interface on which a molecular thermodynamical approach can be conducted in order to estimate the number of water molecules coadsorbed with glycine.⁸³ This can be achieved by calculating free energies of adsorption from the liquid phase with an a posteriori treatment based on atomistic thermodynamics. In this approach chemical potentials of the reactants and products in the liquid phase are estimated.⁸¹

The free energies of glycine and water coadsorption are estimated to -16 and $+12$ kJ/mol in the case of addition of one water molecule at the NH_3^+ end, and addition of two water molecules at the carboxylate end, respectively. To summarize, the interaction of glycine with amorphous silica is predicted to occur via its ammonium group through one water molecule, whereas a direct interaction via the carboxylate group with the surface is favored.

It is interesting to notice that Ben Shir et al.⁸ concluded from NMR experiments that the carboxylate group is mobile and does not interact with the silica surface, while the ammonium group is tightly bond via three hydrogen bonds to the silanols of the silica surface. They described their rate of hydration to be intermediate, whereas in relatively dry conditions the carboxylate group is energetically predicted to be adsorbed on the surface. The theoretical model presented in this work, aimed to describe low hydration rates (microsolvation), might not be hydrated enough to represent the experimental adsorption conditions. The presence of water around the glycine molecule and on the silica surface might generate entropically favored configurations, ruling over the enthalpically favored ones, a situation already proposed in the interaction of a phospholipid on a silica surface.⁴⁴

The present results point out that (i) geminal silanols “per se” do not have an increased reactivity in comparison to vicinal silanols; (ii) instead they participate in creating a “silanol nest”, a local region of high silanol density, which exhibits an increased reactivity toward glycine; (iii) glycine adsorption on a “silanol nest” is significantly more exothermic, than on vicinal silanols; (iv) this result is valid also when water is coadsorbed with glycine, and (v) water coadsorbs preferentially at the NH_3^+ moiety of glycine, in agreement with previous studies.^{10,37}

3.4. NMR Calculations. Calculations of NMR parameters were performed on four configurations of glycine adsorption on the surface (Figure 9): (i) Glycine carboxylate forming two H-bonds with two geminal silanols (config I, Figure 5b); (ii)

glycine carboxylate forming two H-bonds with two vicinal silanols (config II, Figure 4c); (iii) glycine carboxylate forming two H-bonds with two geminal silanols via two interfacial water molecules (config III, Figure 7a); (iv) glycine carboxylate forming two H-bonds with two vicinal silanols via two interfacial water molecules (config IV, Figure 7b).

The corresponding calculated ^1H , ^{13}C , and ^{15}N NMR chemical shift values are summarized in Table 2.

^{13}C and ^{15}N chemical shift values calculated for the different adsorption configurations (shown in Figure 9) were positioned on a theoretical two-dimensional map, in regard with the experimental ^{13}C and ^{15}N spectra (Figure 10). It must be underlined that this figure is not an experimental 2D NMR map. The calculated chemical shifts of the three polymorphs of glycine are also shown as references. It appears that all adsorption configurations yield NMR parameters consistent with the experimental signals previously assigned to glycine in interaction with the silica surface, and separate from the parameters of bulk glycine (at least along the ^{13}C chemical shift dimension), giving confidence in the used methodology. Additional data are necessary to determine whether one of the various models is more relevant than the others from the NMR point of view. Therefore, attention was then focused on the calculated ^1H chemical shifts of ammonium protons of glycine and on silanol/water protons interacting with glycine (Figure 11). Apart from configuration III, the $-\text{NH}_3^+$ protons show chemical shifts smaller than in glycine polymorphs⁸⁰ (8.0 ppm for α - and γ -glycine, and 8.9 ppm for β -glycine), in good agreement with the experimental value of 6.4 ppm extracted from the ^1H – ^{15}N HETCOR CP MAS NMR experiment. For configurations I and III, the $\delta_{\text{iso}}(^1\text{H})$ of silanols H-bonded to the carboxyl oxygens of glycine are very high (between 9.4 and 9.7 ppm) which is most probably related to very short $\text{OH}\cdots\text{O}$ distances (between 1.56 and 1.66 Å). Indeed, a correlation between proton chemical shift of silanols and the H-bond network has been reported previously.⁴⁷ For the vicinal configurations, $\delta_{\text{iso}}(^1\text{H})$ of silanols or water molecules H-bonded to the COO^- group are smaller (between 5.1 and 6.5 ppm) and the corresponding $\text{OH}\cdots\text{O}$ distances are longer (between 1.70 and 1.74 Å). The latter values are in better agreement with the experimental values extracted from the ^1H – ^{13}C and ^1H – ^{29}Si HETCOR CP MAS NMR experiment.

All in all, the best agreement between experimental and calculated NMR data is obtained for configurations II and IV,

Table 2. Comparison between Experimental and Calculated NMR ^1H , ^{13}C and ^{15}N Chemical Shift Values for Various Adsorption Configurations of Glycine on the Silica Surface

glycine site	δ_{iso} (ppm)				
	exp	Config I (5b)	Config II (4c)	Config III (7a)	Config IV (7b)
COO^-	173.6–171.5	173.2	170.9	170.9	169.2
NH_3	–348.5	–349.3	–348.0	–349.2	–348.5
NH_3	6.4	7.0	7.3	8.1	7.5
$-\text{OH}$ (SiOH or H_2O) interacting with COO^-	4.2–5.0	9.5; 9.7	5.8; 6.4	9.4; 9.6	5.7; 6.9

corresponding to the adsorption on vicinal silanols: this is interesting because these are much more abundant than geminal sites according to the ^{29}Si MAS NMR spectrum of the sample showing 2.7% au Q_2 (geminal silanols), 23.9% of Q_3 (vicinal silanols), and 71.4% of Q_4 (fully condensed $\text{Si}(\text{OSi})_4$) sites (Supporting Information Figure S4). Nonetheless, considering the accuracy of experimental results, all calculated NMR shifts fall within the experimental range suggesting that a distribution of adsorption configurations cannot be excluded.

4. CONCLUSIONS

DFT-D calculations have been performed on a model amorphous silica surface, in order to help interpreting experimental NMR data. Several typical configurations were considered, where glycine was adsorbed on vicinal or geminal silanols, without and with water coadsorption. ^{13}C and ^{15}N NMR signal corresponding to the relatively rigid glycine molecules interacting with the silica surface could be clearly identified by combining CP experiments and NMR calculations on the models. Moreover, it appears that the best site for adsorption configuration was the silanol nest, and that water coadsorption was favored, especially concerning the ammonium entity. Calculated NMR shifts fall into the experimental range with a slightly better agreement for adsorption configurations on vicinal silanols, which are present in majority on this silica. However, contributions from zones of high local density of silanols cannot be excluded.

Finally, we notice that our representative silica model exposes sites of very different reactivity, and is thus useful to explore different possibilities of adsorption, at low computational cost. Comparison with experimental data may be done by extracting data on particular sites that are known to be present on real surfaces. Obviously, our results are more indicative of tendencies than precise assignments. In particular, the electronic energy of the system is not the only criteria to discriminate between different adsorption scenarios. One might describe a very stable site and adsorption configuration on the basis of its energy but, due to its small probability of presence on the surface (as for example geminal silanols in MCM-41 sample), it may not be the most representative adsorption situation. The presence of the surface sites is dependent on the synthesis protocol of the silica material. Another unknown condition of adsorption is the accessibility of the surface site for the glycine molecule. The adsorbent may be blocked by steric hindrance. The role of the solvent is also a parameter to be considered, and will be the subject of future works.

Figure 1. ^{13}C CP MAS NMR spectra of the glycine polymorphs (α -glycine, blue; β -glycine, green; γ -glycine, red) and Gly/MCM (black line).

Figure 2. HETCOR CP MAS NMR spectra: (a) ^{13}C - $\{^1\text{H}\}$, (b) ^{15}N - $\{^1\text{H}\}$, and (c) ^{29}Si - $\{^1\text{H}\}$ of Gly/MCM. ^1H projections for specific ^{13}C , ^{15}N , or ^{29}Si chemical shifts are presented on the right side of the figure.

Figure 3. ^{15}N CP MAS NMR spectra of the glycine polymorphs: α -glycine (blue line), β -glycine (green line), γ -glycine (red line), and glycine encapsulated in mesoporous silica (black line).

Figure 5. Configurations obtained for glycine in interaction with geminal silanols, forming two H-bonds from the COO^- end with the geminal pair (a), and an additional bond from the NH_3^+ end with a more distant silanol (b).

Figure 7. Optimized geometries of glycine coadsorbed with three water molecules on silica (a) on geminal silanols and (b) on a pair of vicinal silanols. (Dispersion corrected energies in parentheses.)

Figure 4. Configurations obtained for glycine in interaction with a pair of vicinal silanols, forming (a) one H-bond, (b) two H-bonds, and (c,d) three H-bonds with the surface.

Figure 6. Configurations corresponding to zwitterionic glycine on silica (Figures 4e and 5b), but where the SiOH have been replaced by water molecules, the O atoms being fixed and the “healing” H atoms relaxed. The stabilization energy of glycine in those water clusters is given in kJ/mol.

Figure 8. Optimized geometries of glycine coadsorbed with 1 water molecule on silica. (Dispersion corrected energies in parentheses.)

Figure 9. Calculated ^{13}C et ^{15}N NMR chemical shift values for various configurations of glycine adsorption on the silica surface: (a) glycine carboxylate in interaction with geminal silanols, (b) glycine carboxylate in interaction with vicinal silanols, (c) glycine carboxylate in interaction with geminal silanols in the presence of interfacial water, and (d) glycine carboxylate in interaction with vicinal silanols in the presence of interfacial water.

Figure 10. Theoretical two-dimensional map correlating ^{13}C and ^{15}N spectra of the encapsulated glycine and positioning calculated ^{13}C and ^{15}N chemical shift values for the different adsorption configurations and for glycine polymorphs.

Figure 11. Calculated ^1H NMR parameters of silanols/water molecules in interaction with the carboxylate for various configurations of glycine adsorption on the silica surface: (a) glycine carboxylate in interaction with geminal silanols, (b) glycine carboxylate in interaction with vicinal silanols, (c) glycine carboxylate in interaction with geminal silanols in the presence of interfacial water, and (d) glycine carboxylate in interaction with vicinal silanols in the presence of interfacial water.
