Abstract

The influence of a time-periodic forcing on stochastic processes can essentially be emphasized in the large time behaviour of their paths. The statistics of transition in a simple Markov chain model permits to quantify this influence. In particular a functional Central Limit Theorem can be proven for the number of transitions between two states chosen in the whole finite state space of the Markov chain. An application to the stochastic resonance is presented.

Key words and phrases: Markov chain, Floquet multipliers, central limit theorem, large time asymptotic, stochastic resonance.

Introduction

The description of natural phenomenon sometimes requires to introduce stochastic models with periodic forcing. The simplest model used to interpret for instance the abrupt changes between cold and warm ages in paleoclimatic data is a one-dimensional diffusion process with time-periodic drift [6]. This periodic forcing is directly related to the variation of the solar constant (Milankovitch cycles). In the neuroscience framework, such periodic forced model is also of prime importance: the firing of a single neuron stimulated by a periodic input signal can be represented by the first passage time of a periodically driven Ornstein-Uhlenbeck process [18] or other extended models [13]. Moreover let us note that seasonal autoregressive moving average models have been introduced in order to analyse and forecast statistical time series with periodic forcing. Recently the time dependence of the volatility in financial time series leded to emphasize periodic autoregressive conditional heteroscedastic models. Whereas several statistical models permit to deal with time series, the influence of periodic forcing on time-continuous stochastic processes concerns only few mathematical studies. Let us note a nice reference in the physics literature dealing with this research subject [12].

Therefore we propose to study a simple Markov chain model evolving in a time-periodic environment (already introduced in the stochastic resonance
context [11] and [9]) and in particular to focus our attention to its large time asymptotic behaviour. Since the dynamics of the Markov chain is not time-homogeneous, the classical convergence towards the invariant measure and the related convergence rate cannot be used.

**Description of the model.** Let us consider a time-continuous irreducible Markov chain evolving in the state space $S = \{s_1, s_2, \ldots, s_d\}$ with $d \geq 2$. The transition rate from state $s_i$ to state $s_j$ is denoted by $\varphi_{i,j}$. We assume that $\varphi_{i,j} \geq c$ for some positive constant $c$ and for any $i$ and $j$. We perturb this initial process by a periodic forcing of period $T$; it means that the transition rates $\varphi_{i,j}^T$ are increased using additional non-negative periodic functions $\varphi_{i,j}^T$. The obtained Markov chain is denoted by $(X_t)_{t\geq 0}$ and its infinitesimal generator is given by

$$Q_t = \begin{pmatrix}
-\varphi_{1,1}(t) & \varphi_{2,1}(t) & \cdots & \varphi_{d,1}(t) \\
\varphi_{1,2}(t) & -\varphi_{2,2}(t) & \cdots & \varphi_{d,2}(t) \\
\vdots & \vdots & \ddots & \vdots \\
\varphi_{1,d}(t) & \varphi_{2,d}(t) & \cdots & -\varphi_{d,d}(t)
\end{pmatrix}, \quad (0.1)
$$

Here $\varphi_{i,j} = \varphi_{i,j}^0 + \varphi_{i,j}^T$ are $T$-periodic functions representing the transition rate from state $s_i$ to $s_j$. In particular, the transitions rates satisfy:

$$\varphi_{i,j}(t) \geq c > 0 \quad \text{for any } (i, j) \in S^2. \quad (H)$$

We also assume that $\varphi_{i,j}$ are càdlàg functions.

In order to describe precisely the paths of the chain $(X_t)$, we define transitions statistics: $N_{t}^{i,j}$ corresponds to the number of switching from state $s_i$ to $s_j$ up to time $t$. For notational convenience, we focus our attention to $\mathcal{N}_{t} := N_{t}^{1,2}$. Obviously knowing the processes $(\mathcal{N}_{t}^{i,j})$ for any $1 \leq i, j \leq d$ is equivalent to know the behaviour of $(X_t)$.

**Main result.** Let us first note that, in the higher dimensional space $[0, T] \times S$, we can define a Markov process $(t \mod T, X_t)_{t \geq 0}$ which is time-homogeneous and admits a unique invariant measure $\mu = (\mu_i(t))_{1 \leq i \leq d, t \in [0, T]}$. The main results can then be stated. The periodic forcing implies that the distribution of the Markov chain $(X_t)$ converges as time elapses toward the unique invariant measure $\mu$ (the sense of this convergence is made precise in Section 1). Moreover the first moments of the statistics $\mathcal{N}_t$ satisfy:

$$\lim_{t \to \infty} \frac{1}{t} \mathbb{E}[\mathcal{N}_t] = \frac{1}{T} \int_0^T \varphi_{1,2}(s) \mu_1(s) \, ds,$$

and there exists a constant $\kappa_\varphi > 0$ such that $\lim_{t \to \infty} \text{Var}(\mathcal{N}_t)/t = \kappa_\varphi$. The explicit value of the constant $\kappa_\varphi$ is emphasized in Section 2.1. Using these two moment asymptotics, we can prove a Central Limit Theorem: the number of transitions between two given states during $n$ periods is asymptotically gaussian distributed: the process

$$\left( \frac{\mathcal{N}_{ntT} - \mathbb{E}[\mathcal{N}_{ntT}]}{\sqrt{\text{Var}(\mathcal{N}_{ntT})}} \right)_{0 \leq t \leq 1}$$

converges in distribution towards the standard Brownian motion as $n$ tends to infinity (Theorem 2.6).
Application. The explicit expression of the mean number of transition between two states before time $t$ permits to deal with particular optimization problems appearing in the stochastic resonance framework (see, for instance, [8]). Let us reduce the study to a 2-state space: $S = \{s_1, s_2\}$ and to the corresponding Markov chain whose transition rates correspond to $\varphi_{1,2}$ respectively $\varphi_{2,1}$, the exit rate of the state $s_1$ resp. $s_2$. Let us consider a family of periodic forcing having all the same period $T$ and being parametrized by a variable $\epsilon$, then it is possible to choose in this family the perturbation which has the most influence on the stochastic process, just by minimizing the following quality measure:

$$M(\epsilon) := \left| \int_0^T \varphi_{1,2}^\epsilon(s) \mu^\epsilon_1(s) ds - 1 \right|.$$ 

Indeed this expression intuitively means that the asymptotic number of transitions from state $s_1$ to state $s_2$ is close to 1. In Section 3 we shall compare this quality measure (already introduced in [20]) to other measures usually used in the physics literature [11].

1 Periodic stationary measure for Markov chains

Before focusing our attention to the paths behaviour of the Markov chain, we describe, in this preliminary section, the fixed time distribution of the random process and, in particular, analyse the existence of a so-called periodic stationary probability measure – PSPM (we shall precise this terminology in the following). The distribution of the Markov chain $(X_t)_{t \geq 0}$ starting from the initial distribution $\nu_0$ and evolving in the state space $S = \{s_1, \ldots, s_d\}$ is characterized by

$$\nu_i(t) = \mathbb{P}_{\nu_0}(X_t = s_i), \quad 1 \leq i \leq d.$$ 

This probability measure $\nu = (\nu_1, \ldots, \nu_d)^*$ (the symbol $*$ stands for the transpose) constitutes a solution to the following ode:

$$\dot{\nu}(t) = Q_t \nu(t) \quad \text{and} \quad \nu(0) = \nu_0, \quad (1.1)$$

where the generator $Q_t$ is defined in (0.1). Let us just note that

$$\mathbb{P}(X_{t+h} = s_j | X_t = s_i) = \varphi_{i,j}(t) h + o(h)$$

for $i \neq j$. Moreover the following relation holds

$$\varphi_{i,i} = \sum_{j=1, j \neq i}^d \varphi_{1,j}, \quad \forall 1 \leq i \leq d. \quad (1.2)$$

Floquet’s theory dealing with linear differential equation with periodic coefficients can thus be applied. In particular we shall prove that $\nu(t)$ converges exponentially fast towards a periodic solution of (1.1), the convergence rate being related to the Floquet multipliers (see Section 2.4 in [4]).

Definition 1.1. Any $T$-periodic solution $\nu(t) = (\nu_1, \ldots, \nu_d)^*$ of (1.1) is called a periodic stationary probability measure – PSPM iff $\nu_i(t) \geq 0$ for all $i \in \{1, \ldots, d\}$ and $\sum_{i=1}^d \nu_i(t) = 1$ both for all $t \geq 0$. 

3
The following statement points out the long time asymptotics of the Markov chain.

**Theorem 1.2.** The system (1.1) has a unique stationary probability measure \( \mu(t) \) which is \( T \)-periodic. For any initial condition \( \nu_0 \), the probability distribution \( \nu(t) := \mathbb{P}_{X_t} \) converges in the large time limit towards \( \mu(t) \). More precisely the rate of convergence is given by

\[
\lim_{t \to \infty} \frac{1}{t} \log \| \nu(t) - \mu(t) \| \leq \text{Re}(\lambda_2) < 0, \tag{1.3}
\]

where \( \lambda_2 \) is the second Floquet exponent associated to (1.1) and (0.1); \( \| \cdot \| \) stands for the Euclidean norm in \( \mathbb{R}^d \).

**Proof.** Step 1. Existence of the periodic invariant measure. We consider the distribution of the Markov chain \( (X_t) \) starting from state \( s_i \), we obtain obviously a probability measure which is solution of the following ode:

\[
\dot{\nu}^i(t) = Q_i \nu^i(t), \quad \nu^i(0) = (\delta_{ij})_{j \in \{1, \ldots, d\}}, \tag{1.4}
\]

where \( \delta_{ij} \) stands for the Kronecker symbol. We deduce that the principal matrix solution of (1.1) is given by

\[
M(t) = \begin{pmatrix}
\nu_1^1(t) & \nu_2^1(t) & \cdots & \nu_s^1(t) \\
\nu_1^2(t) & \nu_2^2(t) & & \nu_s^2(t) \\
& \ddots & \ddots & \vdots \\
\nu_1^d(t) & \nu_2^d(t) & \cdots & \nu_s^d(t)
\end{pmatrix}
\]

since \( M(0) = \text{Id}_d \), the identity matrix in \( \mathbb{R}^d \). The monodromy matrix \( M(T) \) is therefore stochastic and strictly positive: \( \nu_j^i(T) > 0 \) since \( Q_i \) satisfies (H).

By the Perron-Frobenius theorem (see chapter 8 in [14]), the largest eigenvalue is simple and equal to 1. Moreover, the associated eigenvector is strictly positive and so we define a probability measure using a normalisation procedure. Consequently there exists a unique periodic invariant probability measure \( \mu(t) \). Floquet’s theory insures that \( \mu(t) \) is \( T \)-periodic.

Step 2. Convergence. By the Perron-Frobenius theorem, the eigenvalues of the monodromy matrix \( M(T) \), also called Floquet multipliers, are \( \{r_1, r_2, \ldots, r_s\} \), \( s \leq d \) with \( 1 = r_1 > |r_2| \geq |r_3| \geq \ldots \geq |r_s| \) and whose associated multiplicity \( n_1, \ldots, n_s \) satisfy \( n_1 = 1 \) and \( \sum_{k=1}^s n_k = d \). Let us decompose the space as follows \( \mathbb{R}^d = \mathbb{R} \mu(0) \oplus V \) where \( \mu(0) \) is the periodic invariant measure at time \( t = 0 \) and \( V \) is a stable subspace for the linear operator \( M(T) \). Since the first eigenvalue \( r_1 \) is simple, the spectral radius of \( M(T) \) restricted to the subspace \( V \) satisfies \( \rho(M(T)|_V) = |r_2| < 1 \). So for any probability distribution \( \nu_0 \), we get \( \nu_0 = \alpha \mu(0) + v \) with \( \alpha \in \mathbb{R} \) and \( v \in V \). Hence

\[
\| M(T)^n \nu_0 - \alpha \mu(0) \| = \left\| \left( M(T)|_V \right)^n v \right\| \leq \left\| \left( M(T)|_V \right)^n \right\| \cdot \| v \|.
\]

Using Gelfand’s formula (see, for instance [19], p.70) we obtain the asymptotic result

\[
\lim_{n \to \infty} \frac{1}{n} \log \| M(T)^n \nu_0 - \alpha \mu(0) \| \leq \log(|r_2|) < 0. \tag{1.5}
\]
In particular, since $M(T)^n \nu_0$ is a probability measure, we deduce that $\alpha = 1$. Let us just note that the Floquet multiplier $r_2$ satisfies $r_2 = e^{i\lambda_2 T}$ where $\lambda_2$ is the associated Floquet exponent defined modulo $2\pi/T$. Consequently

$$\log(|r_2|) = T \Re(\lambda_2).$$

Let us now consider any time $t$, $\nu(t)$ is then a probability measure satisfying

$$\nu(t) = M(t)\nu_0.$$

We define $r(t) \in [0, T]$ by $r(t) = t - [t/T] T$ and obtain

$$\|\nu(t) - \mu(t)\| = \|M(t)\nu_0 - M(t)\mu_0\|
= \|M(r(t))M([t/T]T)\nu_0 - M(r(t))\mu_0\|
\leq \|M(r(t))\| \left\|M(T)^{[t/T]}\nu_0 - \mu_0\right\|.$$

By (1.5) and since $M(t)$ is a continuous and $T$-periodic function (bounded operator), we obtain the announced statement (1.3).

**The particular 2-dimensional case**

In this section, we focus our attention to the particular 2-dimensional case. As explained in Theorem 1.2, the distribution of the Markov chain $\nu(t) := \mathbb{P}_X t$, starting from the initial distribution $\nu_0$ and evolving in the state space $S = \{s_1, s_2\}$ converges exponentially fast to the unique PSPM $\mu$. In dimension 2, we can compute explicitly the probability measure $\nu(t)$ and the convergence rate, applying Floquet’s theory. This theory deals with linear differential equation with periodic coefficients (see Section 2.4 in [4]). The following statement points out the long time asymptotics of the Markov chain.

**Proposition 1.3.** In the large time limit, the probability distribution $\nu$ converges towards the unique PSPM $\mu$ defined by $\mu(t) = (\mu_1(t), 1 - \mu_1(t))$ and

$$\mu_1(t) = \mu_1(0)e^{-\int_0^t(\phi_{1,2} + \phi_{2,1})(s)ds} + \int_0^t \phi_{2,1}(s) e^{-\int_s^t(\phi_{1,2} + \phi_{2,1})(u)du}ds,$$  \hspace{1cm} (1.6)

where

$$\mu_1(0) = \frac{I(\phi_{2,1})}{I(\phi_{1,2} + \phi_{2,1})} \quad \text{and} \quad I(f) = \int_0^T f(t)e^{-\int_0^T(\phi_{1,2} + \phi_{2,1})(u)du}dt.$$  \hspace{1cm} (1.7)

More precisely, if $\nu(0) \neq \mu(0)$ then

$$\lim_{t \to \infty} \frac{1}{t} \log \|\nu(t) - \mu(t)\| = \lambda_2,$$  \hspace{1cm} (1.8)

where $\lambda_2$ stands for the second Floquet exponent:

$$\lambda_2 = \frac{1}{T} \int_0^T (\phi_{1,2} + \phi_{2,1})(t)dt.$$  \hspace{1cm} (1.9)

**Remark 1.4.** It is possible to transform $(X_t)_{t \geq 0}$ into a time-homogeneous Markov process just by increasing the space dimension. By this procedure $(\mu(t))_{0 \leq t < T}$ becomes the invariant probability measure of $(t \mod T, X_t)_{t \geq 0}$. 

Proof. 1. First we study the existence of a unique PSPM. Let \( \mu(t) \) be a probability measure thus \( \mu_1(t) + \mu_2(t) = 1 \). If \( \mu \) satisfies (1.1) then we obtain, by substitution, the differential equation:

\[
\dot{\mu}_1(t) = -\varphi_{1,2}(t)\mu_1(t) + \varphi_{2,1}(t)(1 - \mu_1(t)).
\]

This equation can be solved using the variation of the parameters. The procedure yields (1.6). The periodicity of the solution requires \( \mu_1(T) = \mu_1(0) \) and leads to (1.7).

2. The system (1.1) admits two Floquet multipliers \( \rho_1 \) and \( \rho_2 \). Since there exists a periodic solution, one of the multipliers (let’s say \( \rho_1 \)) is equal to 1 and we can compute the other one using the relation between the product \( \rho_1 \rho_2 \) and the trace of \( Q_T \):

\[
\rho_1 \rho_2 = \exp \left( \int_0^T \text{tr}(Q_t) \, dt \right).
\]

The explicit expression of the trace leads to (1.9). Let us just note that we can link to both Floquet multipliers \( \rho_1 \) and \( \rho_2 \) the so-called Floquet exponents \( \lambda_1 \) and \( \lambda_2 \) defined (not uniquely) by

\[
\rho_1 = e^{\lambda_1 T} \quad \text{and} \quad \rho_2 = e^{\lambda_2 T}.
\]

3. Since the Floquet multipliers are different, each multiplier is associated with a particular solution of (1.1). \( \rho_1 = 1 \) (i.e. \( \lambda_1 = 0 \)) corresponds to the PSPM since \( \mu(t+T) = \rho_1 \mu(t) \) for all \( t \in \mathbb{R}_+ \). For the Floquet exponent \( \lambda_2 \), we consider \( \zeta(t) \) the solution of (1.1) with initial condition \( \zeta(0)^* = (-1,1) \). Combining both equations of (1.1), we obtain

\[
\begin{align*}
\zeta_1(t) + \zeta_2(t) &= 0, \\
\zeta_1(t) - \zeta_2(t) &= -2 \exp \left( -\int_0^t (\varphi_{1,2} + \varphi_{2,1})(s) \, ds \right). 
\end{align*}
\]

We deduce

\[
\zeta(t)^* = \left( -\exp \left( -\int_0^t (\varphi_{1,2} + \varphi_{2,1})(s) \, ds \right), \exp \left( -\int_0^t (\varphi_{1,2} + \varphi_{2,1})(s) \, ds \right) \right)
\]

and we can easily check that \( \zeta(t+T) = \zeta(t)e^{\lambda_2 T} \).

The solution of (1.1) with any initial condition is therefore a linear combination of \( \zeta \) and \( \mu \), the solutions associated with the Floquet multipliers. Writing \( \nu(0) \) in the basis \( (\mu(0), \zeta(0)) \) yields \( \nu(t) = \alpha \mu(t) + \beta \zeta(t) \), with \( \alpha = \nu_1(0) + \nu_2(0) \) (equal to 1 in the particular probability measure case) and

\[
\beta = \frac{\nu_1(0) - \nu_2(0)}{2} + \frac{I(\varphi_{2,1}) - I(\varphi_{1,2})}{2I(\varphi_{1,2} + \varphi_{2,1})}.
\]

Then, if the initial condition is a probability measure, we obtain (1.8) since

\[
\|\nu(t) - \mu(t)\| = \|\beta \zeta(t)\| = \sqrt{2} |\beta| e^{-\int_0^t (\varphi_{1,2} + \varphi_{2,1})(s) \, ds}.
\]
2 Statistics of the number of transitions

In this section, we aim to describe the number of transitions $N_{i,j}^t$, up to time $t$, between two given states $s_i$ and $s_j$. This information is of prime interest since computing it for a given path is very simple [16]. Recent studies emphasize how to get the probability distribution of this counting process, even in some more general situations: Markov renewal processes including namely the time-homogeneous Markov chains [3].

Moreover counting the transitions permits to get informations about the transition rates of the Markov chain. In the particular time-homogeneous case, the number of transitions during some large time interval are used for estimation purposes (for continuous-time Markov chains see, for instance, [1] and for time discrete Markov chains [2]).

In general, the large time behaviour of $N_{i,j}^t$ is directly related to the ergodic theorem, the law of large numbers and finally the Central Limit Theorem (for precise hypotheses concerning these limit theorems, see [15]). Let us just discuss a particular situation: the study of a time-discrete Markov chain $(X_n)_{n \geq 0}$ with values in the state space $S = \{s_1, \ldots, s_d\}$ and with transition probabilities $\pi$. Let us denote $\mu$ its invariant probability measure. In order to describe the number of transitions, we introduce a new Markov chain by defining $Z_n := (X_{n-1}, X_n)$ for $n \geq 1$, valued in the state space $S^2$. Its invariant measure is therefore $\tilde{\mu}$ defined by

$$\tilde{\mu}(x,y) := \pi(x,y)\mu(x), \quad (x,y) \in S^2.$$  

In this particular situation, the number of transitions of the chain $(X_n)$ is given by

$$\Lambda_n^{1,2} = \sum_{k=1}^n 1\{X_{k-1} = s_1, X_k = s_2\} = \sum_{k=1}^n 1_{(s_1,s_2)}(Z_k).$$

In other words, it corresponds to the number of visits of the state $(s_1,s_2)$ by the chain $(Z_n)_{n \geq 1}$. Consequently, under suitable conditions, the ergodic theorem can be applied:

$$\lim_{n \to \infty} \frac{\Lambda_n^{1,2}}{n} = \tilde{\mu}(s_1,s_2) \quad \text{almost surely.}$$

The Central Limit Theorem precises the rate of convergence.

However these arguments can not be applied directly to the periodic forced Markov chain model associated to the infinitesimal generator (0.1) due to essentially two facts:

- the Markov chain $(X_t)_{t \geq 0}$ is time-inhomogeneous
- the Markov chain is a time-continuous stochastic process.

One way to overcome these difficulties is to combine a discrete time-splitting $(t_n)_{n \geq 0}$ on one hand and an increase of the space dimension on the other hand so that $(t_n \mod T, X_{t_{n-1}}, X_{t_n})$ becomes homogeneous. This procedure seems to be complicated and we choose to present a quite different approach based on a time-splitting and on a functional Central Limit Theorem for weakly dependent random variables introduced by Herrndorf [10]. This results requires to study the asymptotic behaviour of the first moments of $N_t^{i,j}$ and a mixing property of
the Markov chain.
Let us also mention that usually the Central Limit Theorem and the associated
large deviations could be proven using asymptotic properties of the Laplace
transform of $N_{i,j}$. Of course such information is not sufficient for a functional
CLT. An overview of the conditions can be found in [5].

2.1 Long time asymptotics for the average and the variance

The general $d$-dimensional case

Let us focus our attention to the two first moments of $N_t$, the number of transition
between two given states, let us say $s_1$ and $s_2$. In a homogeneous continuous
time Markov chain, the average and the variance of $N_t$ grows linearly if the process
starts with the stationary distribution. What happens if the Markov chain
is not homogeneous and in particular, if the transition probabilities depend
periodically on time?

Let us introduce different mathematical quantities which plays a crucial role
in the asymptotic result.

- Let us denote by $M^h(t)$ the fundamental solution of (1.1), that is:
  \[ \dot{M}^h(t) = Q_t M^h(t), \quad M^h(0) = \text{Id}. \]  

- $\Xi(T)$ represents the Jordan canonical form of $M^h(T)$. $P$ is the matrix
  basis of this canonical form: $\Xi(T) = P^{-1} M^h(T) P$. Moreover we denote
  for any $t \geq 0$,
  \[ \Xi(t) = P^{-1} M^h(t) P. \]  

- Three additional notations: the vector $e_1 = (1, 0, \ldots, 0) \in \mathbb{R}^d$ and the
  matrices $\hat{\text{Id}}_{i,j} = 1_{i=j \geq 2}$ for $1 \leq i, j \leq d$ and $(B_t)_{i,j} = \varphi_{1,2}(t) \delta_{i,2} \delta_{j,1}$.

**Theorem 2.1. Asymptotics of the two first moments**

The number of transitions from state $s_1$ to state $s_2$, denoted by $N_t$, satisfies the following asymptotic properties.

1. First moment. For any initial distribution $P_{X_0}$, we observe in the large time
   limit
   \[ m_t := \mathbb{E}[N_t] \sim \int_0^t \varphi_{1,2}(s) \mu_1(s) ds, \]
   where $\mu_1$ is the first coordinate of the periodic stationary measure associated
   with the Markov chain $(X_t)_{t \geq 0}$. In particular,
   \[ \lim_{t \to \infty} \frac{1}{t} \mathbb{E}[N_t] = \frac{1}{T} \int_0^T \varphi_{1,2}(s) \mu_1(s) ds \]  

2. Second moment. Let us denote by $\mathcal{R}_\nu(t) := \text{Var}(N_t) - \mathbb{E}[N_t]$ for the initial
distribution of the Markov chain: $P_{X_0} = \nu$. Then
   \[ \mathcal{R}_{\mu(0)}(T) = 2 \int_0^T \varphi_{1,2}(s) c_1^* P \Xi(s) \text{Id} C(s) ds, \]  

8
Proof.

Step 1.

Averaged number of transitions as follows:

\[ C(t) = \int_0^t \Xi(s)^{-1} P^{-1} B_s \mu(s) \, ds. \]  \hspace{1cm} (2.5)

Moreover the following limit holds

\[ \lim_{t \to \infty} \frac{1}{t} R_{\nu}(t) = \frac{2}{T} \left\{ e_1^T \left( \int_0^T \varphi_{1,2}(s) P \Xi(s) \, ds \right) \Xi(T) \mathbb{1} \left( \mathbb{1} - \Xi(T) \mathbb{1} \right)^{-1} C(T) \right\} \]

\[ + \frac{1}{T} R_{\mu(0)}(T). \]  \hspace{1cm} (2.6)

Remark 2.2. 1. The limit (2.6) does not depend on the initial distribution of \( X_0 \). This property is related to the ergodic behaviour of the Markov chain developed in 1.2.

2. If the fundamental solution of (2.1) at time T is diagonalizable, that is \( r_1 = 1 > r_2 > \ldots > |r_d| \) where \( r_i \) are the Floquet multipliers of (1.1), then (2.6) takes a simpler form due to the following expression:

\[ \left( \Xi(T) \mathbb{1} \left( \mathbb{1} - \Xi(T) \mathbb{1} \right)^{-1} \right)_{i,j} = \frac{r_j}{1 - r_i} 1_{\{i = j \geq 2\}}, \quad 1 \leq i, j \leq d. \]

3. If the transition probabilities are constant functions such that \( Q_t \) defined in (0.1) satisfies

\[ \varphi_{i,j} = \varphi_{i,\{i \neq j\}} - (d-1) \varphi \{i = j\}, \]

for some constant \( \varphi > 0 \), then Theorem 1.2 can be applied for any \( T > 0 \) and straightforward computations lead to:

\[ R_{\mu(0)}(t) = \frac{2}{d^2} (1 - e^{-d\varphi t} - d\varphi t) \]

Hence

\[ \lim_{t \to \infty} \frac{1}{t} R_{\mu(0)}(t) = -\frac{2\varphi}{d^3}. \]

Even in this simple homogeneous situation, \( N_t \) is not asymptotically Poisson distributed. Indeed the Poisson distribution would satisfy \( \mathcal{R}(t) = 0 \).

Proof. Step 1. Averaged number of transitions. Let us first decompose the averaged number of transitions as follows:

\[ m_t = \sum_{k=1}^d m_t^k \quad \text{with} \quad m_t^k = \mathbb{E} [ N_t 1_{X_t = s_k} ] . \]

We set \( \mathcal{M}_t \) as \( (m_t^1, \ldots, m_t^d)^* \). For \( h > 0 \), we get

\[ m_{t+h}^2 = \mathbb{E} [ N_{t+h} 1_{X_{t+h} = s_2} ] = \sum_{1 \leq i \leq d} \mathbb{E} [ (N_t + (N_{t+h} - N_t)) 1_{X_t = s_i, X_{t+h} = s_2} ] \]

\[ = \sum_{1 \leq i \leq d} \mathbb{E} [ N_t 1_{X_t = s_i} ] \mathbb{P} (X_{t+h} = s_2 | X_t = s_i) \]

\[ + \sum_{1 \leq i \leq d} \mathbb{E} [ (N_{t+h} - N_t) 1_{X_t = s_i, X_{t+h} = s_2} ] \]

\[ = m(t)(1 - \varphi_{1,2}(t)h) + \sum_{i=1, i \neq 2}^d m(t)\varphi_{1,2}(t)h + \nu_1(t)\varphi_{1,2}(t)h + o(h) \]
where \( \nu(t) = \mathbb{P}(X_t = s_i) \). By similar computations, we obtain the result for \( h < 0 \). Moreover for \( k \neq 2 \):

\[
    m^h_{t+h} = \mathbb{E}[X_{t+h}1_{\{X_{t+h} = s_k\}}] = m^h(t)(1 - \varphi_{k,k}(t)h) + \sum_{i=1, i \neq k}^d m^t(t, \varphi_{i,k}(t)h) + o(h).
\]

Finally we observe that \( \mathcal{M}_t \) satisfies the ode:

\[
    \mathcal{M}_t = Q_t \mathcal{M}_t + B_t \nu_t, \quad \mathcal{M}_0 = 0, \quad (2.7)
\]

where \((B_t)_{i,j} = \varphi_{1,2}(t)\delta_{i,2}\delta_{j,1}\). Let \( M^h(t) \) the fundamental solution of \((2.1)\). Since \( \mathcal{Q}_t \) satisfies \((H)\), \( M^h(T) \) is an irreducible positive and stochastic matrix. Indeed, let us just explain why \( P_{s_j}(X_T = s_j) > 0 \) for any \( i \) and \( j \): let us assume that this inequality does not hold. Then for \( h \) small enough, there exists a state \( s_l \) such that

\[ P_{s_l}(X_T = s_l) > 0, \quad (2.8) \]

and

\[ P(X_T = s_j|X_{T-h} = s_l) = \varphi_{l,j}(T-h)h + o(h) \quad (2.9) \]

if \( l \neq j \), otherwise:

\[ P(X_T = s_j|X_{T-h} = s_j) = 1 - \varphi_{j,j}(T-h)h + o(h) \quad (2.10) \]

By \((H)\), the combination of \((2.8)\), \((2.9)\) and \((2.10)\) leads to the announced property \( P_{s_j}(X_T = s_j) > 0 \), as a product of two positive quantities. Therefore the Perron-Frobenius theorem (see chapter 8 in [14]) applied to the matrix \( M^h(T) \) implies

- the eigenvalues \( r_1, r_2, \ldots, r_s \) of the matrix \( M^h(T) \) have the associated multiplicity \( n_1 = 1 \), \( \sum_{k=1}^s n_k = d \) and \( r_1 = 1 > |r_2| \geq \ldots |r_s| \).

- the eigenvector associated to the first eigenvalue corresponds to the periodic stationary probability measure \( \mu(0) \).

We denote therefore \( B = (\xi_1^0, \ldots, \xi_d^0) \) the basis of the canonical Jordan form of the matrix \( M^h(T) \) and \( P \) the basis matrix of \( B \), \( P^{-1}M^h(T)P \) being then the Jordan form. In particular \( \xi_1^0 = \mu(0) \). We define \( \xi_k(t) = M^h(t)\xi_k^0, \quad 1 \leq k \leq d \) and observe two different cases: either \( \xi_k^0 \) is an eigenvector of \( M^h(T) \) associated to the eigenvalue \( r_j \) which implies that

\[
    \xi_k(t + T) = M^h(t + T)\xi_k^0 = M^h(t)M^h(T)\xi_k^0 = r_j M^h(t)\xi_k^0 = r_j \xi_k(t) \quad (2.11)
\]

and consequently \( \xi_k \) is a Floquet solution associated to the Floquet multiplier \( r_j \), either \( \xi_k^0 \) is not an eigenvector of \( M^h(T) \) and belongs to the Jordan block associated to the eigenvalue \( r_j \) then

\[
    \xi_k(t + T) = M^h(t)M^h(T)\xi_k^0 = r_j M^h(t)\xi_k^0 + M^h(t)\xi_{k-1}^0 = r_j \xi_k(t) + \xi_{k-1}(t). \quad (2.12)
\]

Furthermore we denote by \( \Xi(t) \) the matrix defined as follows: the coefficient \( \Xi_{i,j}(t) \) represents the \( i \)-th coordinate of the solution \( \xi_j(t) \) in the basis \( B \) for
1 ≤ i, j ≤ d: i.e. Ξ(t) = P^{-1}M^h(t)P. Let us note that since ξ_1 is a probability measure, \{1, \ldots, 1\}ξ_1 = 1. Moreover combining (1.1) and (1.2) leads to the following property: \{1, \ldots, 1\}PΞ(t) is a constant function. If ξ^0_k is an eigenvector of \(M^h(T)\) associated to the eigenvalue \(r_j\) then \(ξ_k(t) = \sum\frac{r_j}{r_j - ξ^0_k}t\) with \(|r_j| < 1\). In particular, since \{1, \ldots, 1\}ξ_1(t) is constant in the canonical basis \{1, \ldots, 1\}ξ_k(t) = 0. If ξ^0_k is not an eigenvector but belongs to the Jordan block associated to the eigenvalue \(r_j\) then (2.12) leads to

\[
(1, \ldots, 1)ξ_k(T) = r_j(1, \ldots, 1)ξ_k(T) + (1, \ldots, 1)ξ_{k−1}((T).
\]

If \(1, \ldots, 1)ξ_{k−1}((T) = 0\) then the property \(|r_j| < 1\) leads to \(1, \ldots, 1)ξ_k(T) = 0\.

So step by step, we prove that

\[
(1, \ldots, 1)PΞ(t) = \sum\frac{r_j}{r_j - ξ^0_k}t\)
\]

Let us now solve the homogeneous part of the equation (2.7): there exists a vector \(C = (C_1, \ldots, C_d)^*\) such that

\[
\mathcal{M}^h_t = PΞ(t)C.
\]

By the method of parameter variation, we obtain the system:

\[
PΞ(t)\dot{C}(t) = B_tν(t) = (0, ϕ_{1,2}(t)ν_1(t), 0, \ldots, 0)^*.
\]

The initial condition \(\mathcal{M}(0) = 0\) leads to \(C(0) = 0\). By multiplying (2.14) on the left side by the vector \(1, \ldots, 1\) we obtain \(\dot{C}_1(t) = ϕ_{1,2}(t)ν_1(t)\). Hence

\[
C_1(t) = \int_0^t ϕ_{1,2}(s)ν_1(s)ds.
\]

We obtain therefore an explicit solution of (2.7) and deduce that

\[
\mathbb{E}[N_t] = (1, \ldots, 1)\mathcal{M}_t = C_1(t) = \int_0^t ϕ_{1,2}(s)ν_1(s)ds ∼ \int_0^t φ_{1,2}(s)PΞ_{1,1}(s)ds,
\]

as \(t\) becomes large. The equivalence presented in the previous equation is due to the ergodic property of the periodically driven Markov chain (Theorem 1.2). More precisely, for any sufficiently small constant \(ε > 0\) (smaller than \(|Re(λ_2)|\) the second Floquet exponent associated with the invariant measure \(μ\)) there exists a constant \(C > 0\) such that:

\[
\mathbb{E}[N_t] − \int_0^t φ_{1,2}(s)PΞ_{1,1}(s)ds \leq \int_0^t φ_{1,2}(s)ν_1(s) − PΞ_{1,1}(s)ds
\]

\[
\leq C\int_0^t φ_{1,2}(s)e^{(Re(λ_2)+ε)s}ds.
\]

\(φ_{1,2}\) is a bounded function, so is the difference \(\mathbb{E}[N_t] − \int_0^t φ_{1,2}(s)PΞ_{1,1}(s)ds\).

**Step 2. Description of the function \(C(t)\).** From now on, we assume that the initial probability measure of the Markov chain is \(μ(0)\), the initial value of the PSPM. Before developing the asymptotics of the variance of \(N_t\) in the large time limit, we need to precise the function \(C(t)\), solution of (2.14) where \(ν_1\) is replaced by \(μ_1\). We know that \(C(0) = 0\). Let us define

\[
η(t) := C(t + T) − C(T) \quad \text{for any} \quad t ≥ 0.
\]
We observe that, due to the periodic property of $\xi$ and $\varphi_{1,2}$, the function $\eta$ is solution of the following equation

$$P \xi(t + T)\dot{\eta}(t) = B_t\xi_1(t), \quad \eta(0) = 0. \quad (2.17)$$

Introducing $\tilde{\eta}(t) = \xi(T)\eta(t)$, we obtain

$$P \xi(t + T)\dot{\eta}(t) = P \xi(t)\xi(T)\dot{\eta}(t) = P \xi(t)\dot{\eta}(t) = B_t\xi(t), \quad \tilde{\eta}(0) = 0.$$ 

By uniqueness of the previous equation (Cauchy-Lipschitz theorem), the equality $\tilde{\eta}(t) = C(t)$ holds. Since $\xi(T)$ is invertible (the Floquet multipliers are not equal to 0):

$$\eta(t) = C(t + T) - C(T) = \xi(T)^{-1}C(t), \quad t \geq 0.$$ 

Therefore, using the definition of $\eta(t)$ and an iteration procedure, we deduce

$$C(t + IT) = \left( \sum_{i=0}^{l-1} \xi(T)^{-1} \right) C(T) + \xi(T)^{-1}C(t), \quad l \geq 1. \quad (2.18)$$

**Step 3. Asymptotics of the variance.** We now describe the asymptotic behaviour of the second moment. Let us denote $V_t = (v_1^t, \ldots, v_n^t)^*$ with $v_1^t = E\xi_1^2 \{ X_i = s \}$. Using similar arguments as those presented in the beginning of Step 1, we obtain the following differential equation:

$$\dot{\hat{V}}_t = Q\hat{V}_t + B_t(2\mathcal{M}_t + \mu(t)), \quad \hat{V}_0 = 0. \quad (2.19)$$

The procedure is similar as above, the variation of parameters leads to:

$$V_t = P \xi(t)\kappa(t) \quad \text{with} \quad \kappa(t) = (\kappa_1(t), \ldots, \kappa_d(t))^*.$$ 

The coefficient $\kappa(t)$ is solution to the equation:

$$P \xi(t)\dot{\kappa}(t) = B_t(2\mathcal{M}_t + \mu(t)), \quad \kappa(0) = 0.$$ 

Multiplying the previous equation on the left side by $(1, \ldots, 1)$ implies:

$$\dot{\kappa}_1(t) = \varphi_{1,2}(t)(2m_1^1 + \mu(t)), \quad \kappa_1(0) = 0.$$ 

The second moment of the number of transitions between the states $s_1$ and $s_2$ satisfies $E_{\mu}[N_t^2] = (1, \ldots, 1)\hat{V}_t = \kappa_1(t)$, that is:

$$E_{\mu}[N_t^2] = \int_0^t \varphi_{1,2}(s)(2m_1^1 + \mu(s)) ds.$$ 

Here $E_{\mu}$ stands for the expectation of the Markov chain distribution with the initial probability distribution $\mu(0)$. Let us set the vector $e_1 = (1, 0, \ldots, 0)^*$ and the matrix $I_{i, j} = 1_{i = j \geq 2}$. On one hand we have

$$E_{\mu}[N_t^2] = \int_0^t \varphi_{1,2}(s)\left(2e_1^*\mathcal{M}_s + \mu_1(s)\right) ds = \int_0^t \varphi_{1,2}(s)\left(2e_1^*P \xi(s)C(s) + \mu_1(s)\right) ds.$$
On the other hand,
\[
\mathbb{E}_\mu [\mathcal{N}_t^2] = \int_0^t 2m'_s m_s \, ds = \int_0^t 2\varphi_{1,2}(s)\mu_1(s)C(s) \, ds
\]
\[
= \int_0^t 2\varphi_{1,2}(s)c_1^*P\Xi(s)(C(s) - \text{Id}^1C(s)) \, ds.
\]
Hence,
\[
\mathcal{R}_{\mu(0)}(t) := \text{Var}_\mu(\mathcal{N}_t) - \mathbb{E}_\mu[\mathcal{N}_t] = 2 \int_0^t \varphi_{1,2}(s)c_1^*P\Xi(s)\text{Id}^1C(s) \, ds. \tag{2.20}
\]

Let us now compute the limit of the following expression \(\mathcal{R}_{\mu(0)}(t)/t\) as \(t \to \infty\).

We first observe that \(\Xi(T)\text{Id}^1\Xi(T)^{-1} = \text{Id}^1\) since \(\Xi(T)\) is a Jordan canonical form with a first eigenvalue which is simple. By (2.18), we obtain, for \(l > 0\),

\[
\Delta(t, l) := P\Xi(t + lT)\text{Id}^1C(t + lT)
\]
\[
= P\Xi(t)P^{-1}(P\Xi(T)P^{-1})^lP\text{Id}^1\left[\left(\sum_{i=0}^{l-1}(\Xi(T)^{-1})^i\right)C(T) + \Xi(T)^{-l}C(t)\right]
\]
\[
= P\Xi(t)\text{Id}^1\sum_{i=1}^l(\Xi(T)^{-1})^iC(T) + P\Xi(t)\text{Id}^1C(t)
\]
\[
= P\Xi(t)\left(\sum_{i=1}^l(\Xi(T)^{-1})^i\right)C(T) + P\Xi(t)\text{Id}^1C(t). \tag{2.21}
\]

The Perron-Frobenius theorem implies that the spectral radius \(\rho(\Xi(T)\text{Id}^1) = |r_2| < 1\). Due to Householder’s theorem (see, for instance, Theorem 4.2.1 in [19]), there exists an induced norm satisfying \(\|\Xi(T)\text{Id}^1\| < 1\). Hence

\[
\|P\Xi(t + lT)\text{Id}^1C(t + lT)\| \leq \frac{\|P\Xi(t)\|}{1 - \|\Xi(T)\text{Id}^1\|} \|C(T)\| + \|P\Xi(t)\text{Id}^1C(t)\|.
\]

The previous upper-bound does not depend on \(l\) and therefore \(t \to P\Xi(t)\text{Id}^1C(t)\) is a bounded function so do \(t \to \varphi_{1,2}(t)c_1^*P\Xi(t)\text{Id}^1C(t)\), the function appearing in the integral (2.20). The limit we need to compute is then given by

\[
\lim_{t \to \infty} \frac{1}{t} \mathcal{R}_{\mu(0)}(t) = \lim_{n \to \infty} \frac{2}{nT} I_n \quad \text{with} \quad I_n = \int_0^{nT} \varphi_{1,2}(s)c_1^*P\Xi(s)\text{Id}^1C(s) \, ds, \tag{2.22}
\]

where \(T\) is the period of \(Q_t\). Let us introduce

\[
\mathbb{I}_0 = \int_0^T \varphi_{1,2}(s)P\Xi(s) \, ds \quad \text{and} \quad \mathbb{I}_1 = \int_0^T \varphi_{1,2}(s)P\Xi(s)\text{Id}^1C(s) \, ds
\]
By (2.21) and since \( \varphi_{1,2} \) is a periodic function, the following splitting holds

\[
I_n = \sum_{k=0}^{n-1} \int_0^T \varphi_{1,2}(s)e_1^* P \Xi(s + kT)\tilde{1}^t C(s + kT) \, ds
\]

\[
= \sum_{k=1}^{n-1} \int_0^T \varphi_{1,2}(s)e_1^* P \Xi(s) \, ds \left( \sum_{i=1}^k (\Xi(T)\tilde{1}^t)^i \right) C(T)
\]

\[
+ n \int_0^T \varphi_{1,2}(s)e_1^* P \Xi(s)\tilde{1}^t C(s) \, ds
\]

\[
= \sum_{k=1}^{n-1} e_1^* \mathbb{I}_0 \left( (\Xi(T)\tilde{1}^t)^1 - (\Xi(T)\tilde{1}^t)^{k+1} \right) \left( \text{Id} - \Xi(T)\tilde{1}^t \right)^{-1} C(T) + ne_1^* \mathbb{I}_1
\]

\[
- e_1^* \mathbb{I}_0 \sum_{k=1}^{n-1} (\Xi(T)\tilde{1}^t)^{k+1} \left( \text{Id} - \Xi(T)\tilde{1}^t \right)^{-1} C(T).
\]

Using the existence of an induced norm satisfying \( \|\Xi(T)\tilde{1}^t\| < 1 \), we deduce that the last term in the previous equality is bounded with respect to the variable \( n \). Consequently (2.22) implies

\[
\lim_{t \to \infty} \frac{1}{t} R_{\mu(0)}(t) = \frac{2}{T} \left\{ e_1^* \mathbb{I}_0 \Xi(T)\tilde{1}^t \left( \text{Id} - \Xi(T)\tilde{1}^t \right)^{-1} C(T) + e_1^* \mathbb{I}_1 \right\}.
\]

**Step 4. Generalization to any initial probability distribution.** To end the proof, we are going to develop the idea that the initial distribution of the Markov chain does not play any role. The first part of the statement (Step 1) implies directly that

\[
\lim_{t \to \infty} \frac{1}{t} E_{\nu}(N_t) = \lim_{t \to \infty} \frac{1}{t} E_{\mu(0)}(N_t).
\]

Let us now observe the variance case. Let \( n \in \mathbb{N}^* \), we introduce

\[
\Delta_n(t) := \Var_{\nu}(N_{nT+t}) - \Var_{\nu(nT)}(N_t),
\]

\[
\Gamma_n(t) := \Var_{\nu(nT)}(N_t) - \Var_{\mu(0)}(N_t),
\]

where \( \nu(nT) \) is the distribution of \( X_{nT} \) with the initial condition \( \mathbb{P}_{X_0} = \nu \). Obviously

\[
\lim_{t \to \infty} \frac{\Var_{\nu}(N_t)}{t} = \lim_{t \to \infty} \frac{\Var_{\mu(0)}(N_t)}{t}.
\]

if

\[
\lim_{n \to \infty} \lim_{t \to \infty} \frac{1}{t} \Delta_n(t) = \lim_{n \to \infty} \lim_{t \to \infty} \frac{1}{t} \Gamma_n(t) = 0.
\]

Using the Markov property, we get

\[
\Var_{\nu}(N_{nT+t}) = \Var_{\nu}(N_{nT} - N_{nT+t}) + \Var_{\nu}(N_{nT}) + 2\cov_{\nu}(N_{nT+t} - N_{nT}, N_{nT})
\]

\[
= \Var_{\nu}(N_{nT}) + \Var_{\nu}(N_{nT}) + 2\cov_{\nu}(N_{nT+t} - N_{nT}, N_{nT}).
\]

(2.25)
Moreover, let us introduce:

\[ K(n, \nu) := \max_{x \in S} \left| \mathbb{E}_x[N_{nT}]X_{nT} = z - \mathbb{E}_x[N_{nT}] \right|. \]

If we denote by \( \mathbb{E}_x \) the expectation under the conditional event \( \{ X_0 = x \} \), we observe that

\[ \overline{\Delta}_n(t) := |\text{Cov}_x(N_{nT+t} - N_{nT}, N_{nT})| \]

\[ = \sum_{x \in S} \mathbb{E}_x[N_t] \left( \mathbb{E}_x[N_{nT}]X_{nT} = x - \mathbb{E}_x[N_{nT}] \right) \nu_x(nT) \]

\[ = \sum_{x \in S} \left( \mathbb{E}_x[N_t] - \mathbb{E}_y(N_{nT}) \right) \left( \mathbb{E}_y[N_{nT}]X_{nT} = x - \mathbb{E}_y[N_{nT}] \right) \nu_y(nT) \]

\[ \leq K(n, \nu) \sum_{(x,y) \in S^2} \mathbb{E}_x[N_t] - \mathbb{E}_y[N_t] \nu_x(nT) \nu_y(nT) \]

\[ \leq 2K(n, \nu) \max_{x \in S} \mathbb{E}_x[N_t] - \mathbb{E}_x(N_0) \nu_x(nT). \]

By (2.3) the normalized averages appearing in the last upper-bound are equivalent in the large time scale, the following asymptotic result therefore holds

\[ \lim_{t \to \infty} \frac{1}{t} \overline{\Delta}_n(t) = 0. \quad (2.26) \]

Consequently, combining (2.25) and (2.26) leads to \( \lim_{t \to \infty} \frac{1}{t} \Delta_n(t) = 0 \). Finally let us prove that \( \lim_{n \to \infty} \lim_{t \to \infty} \Gamma_n(t)/t = 0 \) in order to prove (2.24). Due to the Perron-Frobenius theorem, the PSPM satisfies \( \mu_x(0) > 0 \) for any \( x \in S \) and so, using the definition of \( \Gamma_n \) in (2.23), we obtain

\[ \Gamma_n(t) = \sum_{x \in S} \text{Var}_x(N_t) \left( \left| \frac{\nu_x(nT)}{\mu_x(0)} - 1 \right| \right) \mu_x(0) \]

\[ \leq \frac{\| \nu(nT) - \mu(0) \|}{\min_{x \in S} \mu_x(0)} \text{Var}_{\mu(0)}(N_t) \]

\[ = \frac{\| \nu(nT) - \mu(nT) \|}{\min_{x \in S} \mu_x(0)} \text{Var}_{\mu(0)}(N_t). \]

Combining Step 3 in order to describe the asymptotic behaviour of \( \text{Var}_{\mu(0)}(N_t) \) and Theorem 1.2 permits to imply \( \lim_{n \to \infty} \lim_{t \to \infty} \Gamma_n(t)/t = 0 \) and consequently (2.24).

**The particular 2-dimensional case**

The aim of this section is to express the statement of Theorem 2.1 in the situation \( S = \{ s_1, s_2 \} \). The results obtained in this quite simple situation are not trivial and can be clarified since the explicit expression of the periodic stationary probability measure has been developed in Proposition 1.3.

**Corollary 2.3.** 1. The number of transitions between state \( s_1 \) and state \( s_2 \), denoted by \( N_t \), satisfies

\[ \lim_{t \to \infty} \frac{1}{t} \mathbb{E}[N_t] = \frac{1}{T} \int_0^T \varphi_{1,2}(s) \mu_1(s) \, ds, \]

\[ \text{denoted by} \quad \mathcal{N}_t \text{, satisfies} \]

\[ \lim_{t \to \infty} \frac{1}{t} \mathbb{E}[\mathcal{N}_t] = \frac{1}{T} \int_0^T \varphi_{1,2}(s) \mu_1(s) \, ds, \]
where $(\mu(t))_{t \geq 0}$ is the PSPM (1.6). This result does not depend on the initial distribution of the Markov chain $(X_t)$.

2. Moreover the following large time limit for the variance holds:

$$
\lim_{t \to \infty} \frac{1}{t} \left( \text{Var}(N_t) - \mathbb{E}[N_t] \right) = -\frac{2}{T} \mathbb{J}_1(T) \mathbb{J}_2(1) - \frac{2}{T} \mathbb{J}_2(\mathbb{J}_1).
$$

where $\lambda_2 = -\frac{1}{T} \int_0^T \varphi_{1,2}(t) + \varphi_{2,1}(t) \, dt$ is the second Floquet exponent,

$$
\mathbb{J}_1(t) = \int_0^t \frac{\varphi_{1,2}(s) \mu_1^2(s)}{\zeta_1(s)} \, ds, \quad \mathbb{J}_2(f) := \int_0^T \varphi_{1,2}(s) \zeta_1(s) f(s) \, ds,
$$

$$
\zeta_1(t) = -\exp \left( -\int_0^t (\varphi_{1,2} + \varphi_{2,1})(s) \, ds \right), \quad t \geq 0.
$$

(2.27)

Proof. It suffices to apply Theorem 2.1. Considering the arguments used in Proposition 1.3, we know explicitly the fundamental solution of (2.1). In particular the Jordan canonical form $\Xi(T)$ (defined in (2.2)) is given by

$$
\Xi(T) = \begin{pmatrix} 1 & 0 \\ 0 & e^{\lambda_2 T} \end{pmatrix},
$$

where $\lambda_2$ is defined in (1.9). The Floquet solution associated to the multiplier 1 is the PSPM (1.6) and the Floquet solution associated to the multiplier $e^{\lambda_2 T}$ is $\zeta(t)^* = (\zeta_1(t), -\zeta_1(t))$ with $\zeta_1(t)$ defined in (2.27). We deduce that the basis matrix associated with the Jordan matrix is:

$$
P = \begin{pmatrix} \mu_1(0) & -1 \\ 1 - \mu_1(0) & 1 \end{pmatrix}, \quad \text{with} \quad \mu_1(0) = \frac{I(\varphi_{2,1})}{I(\varphi_{1,2} + \varphi_{2,1})}.
$$

The function $I$ has been defined in (1.7). Consequently

$$
P \Xi(t) = \begin{pmatrix} \mu_1(t) & \zeta_1(t) \\ 1 - \mu_1(t) & -\zeta_1(t) \end{pmatrix}, \quad t \geq 0.
$$

The $\mathbb{R}^2$-valued function $C$ defined by (2.5) is equal to

$$
C_1(t) = \int_0^t \varphi_{1,2}(s) \mu_1(s) \, ds, \quad C_2(t) = -\int_0^t \frac{\mu_1(s)^2 \varphi_{1,2}(s)}{\zeta_1(s)} \, ds.
$$

All these explicit expressions and simple computations combined with (2.4) and (2.6) imply the announced statement.

2.2 Positivity of the limit for the normalized variance

Theorem 2.1 and Corollary 2.4 ensure that the limit, in the large time scale, of the normalized variance $\text{Var}(N_t)/t$ exists. The expression of the limit is quite general and can be computed explicitly in any particular situation. One important property concerning this limit is the positivity. This step is crucial as a preliminary result for the proof of a Central Limit Theorem for the statistics $N_t$. 

\[16\]
Proposition 2.4. Under the hypothesis (H), the long time limit of the normalized variance is positive:
\[
\lim_{t \to \infty} \frac{\text{Var}(N_t)}{t} > 0
\] (2.28)

Proof. Let us decompose \( N_{kT} \) into
\[
N_{kT} = \sum_{j=1}^{k} \Delta N_j \quad \text{with} \quad \Delta N_j = N_{jT} - N_{(j-1)T}.
\]

Using the conditioning with respect to the position of the Markov chain at times \( 0, T, \ldots, kT \), we define \( X_k := (X_0, X_T, \ldots, X_{kT}) \) and obtain
\[
\text{Var}(N_{kT}) = \text{Var} \left( \mathbb{E}[N_{kT}|X_k] \right) + \mathbb{E} \left[ \text{Var}(N_{kT}|X_k) \right] \geq \mathbb{E} \left[ \text{Var}(N_{kT}|X_k) \right].
\] (2.29)

We just recall that the conditional variance is given by:
\[
\text{Var}(N_{kT}|X_k) = \mathbb{E} \left[ (N_{kT} - \mathbb{E}[N_{kT}|X_k])^2 | X_k \right] = \mathbb{E} \left[ \left( \sum_{j=1}^{k} \Delta N_j - \mathbb{E}[\Delta N_j|X_k] \right)^2 | X_k \right].
\]

Developing the square implies:
\[
\text{Var}(N_{kT}|X_k) = \mathbb{E} \left[ \sum_{j=1}^{k} (\Delta N_j - \mathbb{E}[\Delta N_j|X_k])^2 | X_k \right]
+ 2 \sum_{1 \leq j < l \leq k} \mathbb{E} \left[ (\Delta N_j - \mathbb{E}[\Delta N_j|X_k]) (\Delta N_l - \mathbb{E}[\Delta N_l|X_k]) | X_k \right].
\]

Given \( X_k \), the random variables \( \Delta N_j - \mathbb{E}[\Delta N_j|X_k] \) and \( \Delta N_l - \mathbb{E}[\Delta N_l|X_k] \) are independent and centred (for \( 1 \leq j < l \leq k \)). Consequently the double sum in the previous equality vanishes. The Markov property leads to
\[
\text{Var}(N_{kT}|X_k) = \sum_{j=1}^{k} \text{Var}(\Delta N_j|X_k) = \sum_{j=1}^{k} \text{Var}(\Delta N_j|X_{(j-1)T}, X_{jT}).
\]

Let us define the function \( \psi : S \times S \to \mathbb{R}_+ \) by
\[
\psi(a, b) = \text{Var}(\Delta N_j|X_{(j-1)T} = a, X_{jT} = b)
\]
which does not depend on \( j \) since the transition probabilities are \( T \)-periodic. Since the state space is finite, the minimum of the function \( \psi \) is reached. Moreover the random variable \( \Delta N_1 \) knowing both \( X_0 \) and \( X_T \) is not constant a.s. due to the hypothesis (H), so that the following minimum is positive:
\[
V^* = \min_{(a, b) \in S^2} \psi(a, b) > 0.
\]

Therefore the following lower bound holds
\[
\text{Var}(N_{kT}|X_k) \geq kV^* \quad \text{and so} \quad \text{Var}(N_{kT}) \geq kV^*.
\]
just by using (2.29). Dividing by $kT$, we obtain
\[
\lim_{k \to \infty} \frac{\text{Var}(\mathcal{N}_{kT})}{kT} > 0.
\] (2.30)

The statement of Theorem 2.1 points out that the limit considered in (2.28) exists and since the limit of a subsequence (2.30) is positive, we deduce the positivity of (2.28).

2.3 Mixing properties of the time periodic Markov chain

We have already partially described, in the previous results, the behaviour of the Markov chain in the long time limit. The distribution of the Markov chain converges exponentially fast toward the unique periodic stationary probability measure, the normalized (divided by the time variable) averaged number of transitions between two given states converges, so does the normalized variance. All these results concern the one marginal distribution of the Markov chain $(X_t)$ or the one marginal distribution of the counting process $(\mathcal{N}_t)$. In order to complete this study and to better understand the long time behaviour of $X_t$, we are going to prove that the Markov chain $(X_t)_{t \geq 0}$ is weakly correlated, that is, $X_t$ and $X_{t+h}$ are weakly dependent when $h$ is large enough. This property can be measured with a particular tool associated to the strongly mixing concept. This property is quite evident for homogeneous Markov chains, we prove here that it is also satisfied for periodic inhomogeneous Markov chains.

Let us first introduce the $\sigma$-algebra
\[
\mathcal{F}_{i,i+j} = \sigma(\Delta \mathcal{N}_i : i \leq k \leq i+j)
\]
where $\Delta \mathcal{N}_i := \mathcal{N}_{kT} - \mathcal{N}_{(k-1)T}$, and secondly, the mixing coefficients $\alpha_n(k)$ defined, for $k \leq n-1$, by
\[
\alpha_n(k) = \sup \left\{ |\mathbb{P}(A \cap B) - \mathbb{P}(A)\mathbb{P}(B)| : A \in \mathcal{F}_{1,m}, B \in \mathcal{F}_{m+k,n}, 1 \leq m \leq n-k \right\}.
\]

We set $\alpha_n(k) = 0$ for $k \geq n$. These mixing coefficients permit to measure the dependence between random variables belonging to the same sequence. For periodic forced Markov chains, we prove that the dependence of $X_t$ with respect to the initial condition rapidly decreases as time elapses. It is a consequence of the following result.

**Proposition 2.5.** The family of random variables $(\Delta \mathcal{N}_k)_{k \in \mathbb{N}}$ is a strongly mixing sequence, that is
\[
\alpha(k) := \sup_{n \geq 1} \alpha_n(k) = O(b^{-k}) \quad \text{for some } b > 1.
\]

**Proof.** Let $A \in \mathcal{F}_{1,m}$ and $B \in \mathcal{F}_{m+k,n}$, then there exist two measurable bounded and non-negative functions $\psi_A$ and $\psi_B$ such that
\[
1_A = \psi_A(\Delta \mathcal{N}_1, \ldots, \Delta \mathcal{N}_m) \quad \text{and} \quad 1_B = \psi_B(\Delta \mathcal{N}_{m+k}, \ldots, \Delta \mathcal{N}_n).
\]

Then, due to the Markov property, we obtain
\[
\mathbb{P}(A \cap B) = \mathbb{E}[\psi_A(\Delta \mathcal{N}_1, \ldots, \Delta \mathcal{N}_m)\psi_B(\Delta \mathcal{N}_{m+k}, \ldots, \Delta \mathcal{N}_n)]
\]
\[
= \mathbb{E}\left[\psi_A(\Delta \mathcal{N}_1, \ldots, \Delta \mathcal{N}_m)\psi_C(X_{(m+k-1)T})\right],
\]
where $\psi_C$ is a bounded non negative measurable function defined by
\[
\psi_C(x) = E[\psi_B(\Delta N_{m+k}, \ldots, \Delta N_n), X_{(m+k-1)T} = x] = E_x[\psi_B(\Delta N_1, \ldots, \Delta N_{n+1-m-k})].
\]
We deduce that
\[
P(A \cap B) = \mathbb{E}[\psi_A(\Delta N_1, \ldots, \Delta N_m)\psi_C(X_{(m+k-1)T})]
\]
\[
= \sum_{i=1}^d \mathbb{E}[\psi_A(\Delta N_1, \ldots, \Delta N_m)1_{(X_{(m+k-1)T} = s_i)}]\psi_C(s_i)
\]
\[
= \sum_{i,j=1}^d \mathbb{E}[\psi_A(\Delta N_1, \ldots, \Delta N_m)1_{(X_{mT} = s_i)}1_{(X_{(m+k-1)T} = s_j)}]\psi_C(s_i)
\]
\[
= \sum_{i,j=1}^d \mathbb{E}[\psi_A(\Delta N_1, \ldots, \Delta N_m)1_{(X_{mT} = s_j)}]\mathbb{P}(X_{(k-1)T} = s_i)\psi_C(s_i).
\]
By similar computations, we obtain:
\[
\begin{align*}
\mathbb{P}(A) &= \sum_{j=1}^d \mathbb{E}[\psi_A(\Delta N_1, \ldots, \Delta N_m)1_{(X_{mT} = s_j)}], \\
\mathbb{P}(B) &= \sum_{i=1}^d \mathbb{P}(X_{(m+k-1)T} = s_i)\psi_C(s_i).
\end{align*}
\]
Finally $\Delta := |P(A \cap B) - P(A)P(B)|$ is equal to
\[
\Delta = \left| \sum_{i,j=1}^d \mathbb{E}[\psi_A(\Delta N_1, \ldots, \Delta N_m)1_{(X_{mT} = s_j)}]
\times \psi_C(s_i) \left( \mathbb{P}(X_{(m+k-1)T} = s_i) - \mathbb{P}_{s_j}(X_{(k-1)T} = s_i) \right) \right|
\leq \max_{1 \leq i, j \leq d} |\mathbb{P}_{s_i}(X_{(k-1)T} = s_i) - \mathbb{P}_{s_j}(X_{(k-1)T} = s_i)|
\leq 2 \max_{1 \leq i, j \leq d} |\mathbb{P}_{s_i}(X_{(k-1)T} = s_i) - \mu(s_i(0))|
\]
where $\mu(t)$ is the periodic stationary probability measure associated with the chain $(X_t)$. Due to the ergodic property (Theorem 1.2), for any initial probability measure $\nu$ we have
\[
\lim_{t \to \infty} \frac{1}{t} \log \sup_{1 \leq j \leq d} |\mathbb{P}(X_t = s_i) - \mu(s_i(t))| \leq \text{Re}(\lambda_2) < 0,
\]
where $\lambda_2$ is the second Floquet exponent associated with the distribution of the periodically driven Markov chain.

2.4 A Central Limit Theorem for the averaged number of transitions

In this section, we aim to point out the main result of this study. We have already given some description of the long time asymptotics of the number of transitions $N_t$, by computing the two first moments. Moreover the mixing property developed in Proposition 2.5 permits to ensure that the periodic forced Markov chain would behave in a quite similar way as a time-homogeneous Markov chain. In fact, we have to be careful since the law of $X_t$ always depends on the initial condition! (see Theorem 1.2).
Theorem 2.6. Central Limit Theorem. The stochastic process

\[ Z_n(t) := \frac{N_{ntT} - E[N_{ntT}]}{\sqrt{\text{Var}(N_{ntT})}}, \quad t \in [0, 1], \]  

converges in distribution to the standard Brownian motion \((W_t, 0 \leq t \leq 1)\) as \(n \to \infty\).

Proof. Step 1. The arguments developed in the first step of the proof are based on the application of Corollary 2 in [10]. Let us introduce the Markov chain \((Y_n)_{n \geq 1}\) defined by

\[ Y_n = \Delta N_n - E[\Delta N_n], \quad \Delta N_n := N_{ntT} - N_{(n-1)tT}. \]

We just recall this result: the process \(S_n := \sum_{k=1}^{n} Y_k\) satisfies the Central Limit Theorem (2.31) as soon as the following conditions are satisfied:

1. \(E[Y_n] = 0\) and \(E[Y_n^2] < \infty\) for any \(n \geq 1\).
2. The sequence of normalized variances converges as \(n \to \infty\):
   \[ \lim_{n \to \infty} \frac{E[S_n^2]}{n} = \sigma^2 > 0 \quad \text{for some } \sigma > 0. \]
3. There exists \(\beta > 2\) (we set \(\gamma = 2/\beta\)) such that
   \[ \|Y_n\|_\beta = o\left(n^{(1-\gamma)/2}/(\log n)^{1-\gamma/2}\right) \quad \text{and} \quad \alpha(k) = O(b^{-k}), \]
   \[ \text{for some } b > 1 \text{ and } \|Y_n\|_\beta = E^{1/\beta}[|Y_n|^{\beta}]. \]

Under these three conditions, \(W_n(t) := S_{ntT}/(\sigma \sqrt{n})\) converges in distribution towards a standard Brownian motion \(W\). Let us now point out that these conditions are satisfied for the periodic driven Markov chain. The first condition is trivial. The second condition is directly related to the convergence pointed out in Proposition 2.4. Let us now prove (2.32): for all \(1 \leq i, j \leq d\) and \(t \in [0,T]\), \(\varphi_{i,j}(t) \geq 0\) and moreover

\[ M = \max_{t \in [0,T], i \neq j} \varphi_{i,j}(t) > 0. \]

Let us define the Poisson process \((P_t)\) of parameter \(M\) and introduce the upper-bound \(\Delta N_k \leq P_T\). Since all moments of a Poisson process are finite so do the moments of \(\Delta N_k\). We deduce immediately that \(\|Y_n\|_\beta\) is a bounded sequence (the first part of (2.33) is therefore satisfied). Furthermore

\[ E \left[ \frac{(S_{m+n} - S_m)^2}{n} \right] \leq E \left[ \frac{\Delta N_{ntT}^2}{n} \right] \leq MT < \infty, \quad \forall(m,n) \in \mathbb{N}^2. \]

Finally let us note that the second part of (2.33) is an immediate consequence of Proposition 2.5.
**Step 2.** In the first step, the convergence in distribution of $W_n$ towards $W$ was emphasized. Now let us deduce the convergence of $Z_n$ towards $W$. The following splitting holds

$$
N_{ntT} - \mathbb{E}[N_{ntT}] = N_{[nt]T} - \mathbb{E}[N_{[nt]T}] + (N_{ntT} - N_{[nt]T}) - \mathbb{E}[N_{ntT} - N_{[nt]T}].
$$

(2.35)

Let us define the function $U_n : [0, 1] \to \mathbb{N}$ by $U_n(t) = N_{ntT} - N_{[nt]T}$. This function vanishes at any point of the form $k/n$ with $k \in \{0, 1, \ldots, n\}$. Moreover $U_n$ is a non decreasing function on each interval $[(k-1)/n, k/n]$. Hence

$$
\sup_{t \in [0,1]} U_n(t) = \max_{1 \leq k \leq n} \left( \lim_{t \to k/n, t<k/n} U_n(t) \right) \leq \max_{1 \leq k \leq n} \Delta N_k
$$

where $\Delta N_k$ is the total number of transitions observed during the time interval $[(k-1)T, kT]$, $k \in \{1, \ldots, n\}$. This number is stochastically smaller than a Poisson distributed random variable of parameter $\lambda = MT$ where $M$ is defined by (2.34). So we prove that $U_n/\sqrt{n}$ converges in probability to the zero function. Indeed for any $\epsilon > 0$, we set $\delta_n = \epsilon \sqrt{n}$ and obtain

$$
P\left( \max_{1 \leq k \leq n} \Delta N_k \geq \delta_n \right) \leq 1 - \left( \min_{a \in S} \mathbb{P}_a(\Delta N \leq \delta_n) \right)^n \leq 1 - \left( 1 - \sum_{l = \lfloor \delta_n \rfloor + 1}^\infty \frac{\lambda^l e^{-\lambda}}{l!} \right) \leq 1 - \left( 1 - \frac{\lambda^{\lfloor \delta_n \rfloor + 1}}{(\lfloor \delta_n \rfloor + 1)!} \right)^n.
$$

As $n$ goes to $\infty$ the Stirling formula permits to prove that

$$
\lim_{n \to \infty} \left( 1 - \frac{\lambda^{\lfloor \delta_n \rfloor + 1}}{(\lfloor \delta_n \rfloor + 1)!} \right)^n = 1.
$$

Consequently

$$
\lim_{n \to \infty} P\left( \frac{U_n(t)}{\sqrt{n}} \geq \epsilon \right) = 0.
$$

Combining (2.35) with the following convergences as $n \to \infty$:

$$
\frac{N_{[nt]T} - \mathbb{E}[N_{[nt]T}]}{\sigma \sqrt{n}} \xrightarrow{(d)} W_t, \quad \frac{\sigma \sqrt{n}}{\sqrt{\text{Var}(N_{ntT})}} \to 1,
$$

$$
\frac{(N_{ntT} - N_{[nt]T})}{\sigma \sqrt{n}} \xrightarrow{P} 0, \quad \frac{\mathbb{E}[N_{ntT} - N_{[nt]T}]}{\sqrt{\text{Var}(N_{ntT})}} \to 0,
$$

leads to (2.31).

\[\Box\]

### 3 Two examples in the stochastic resonance framework

We seek to describe the phenomenon of stochastic resonance. Let us introduce a continuous-time Markov chain $X_t$ oscillating between two states $\{s_1, s_2\}$ according to a $T$-periodic infinitesimal generator $Q_t$. Then by varying the period,
we observe that the behaviour of the chain changes and adopts more or less periodic paths. The aim in each example is to find the optimal period such that the behaviour of the paths looks like the most periodic as possible. That’s why we shall introduce a criterion which measures the periodicity of any random path. We propose to use a criterion associated with the mean number of transition on a period (it should be also possible to propose a measure based on the minimal variance but we do not adopt this point of view in this study). The interesting tunings correspond to situations where this averaged number is close to the value 1.

3.1 An infinitesimal generator constant on each half period

In this first example, we consider T-periodic rates given by

\[ \varphi_{1,2}(t) = \varphi_0 \mathbf{1}_{[0 < t < T/2]} + \varphi_1 \mathbf{1}_{[T/2 < t < T]} = \varphi_0 + \varphi_1 - \varphi_{2,1}(t). \]  

(3.1)

where \( \varphi_0 = p e^{-\frac{t}{V}} \) et \( \varphi_1 = q e^{-\frac{t}{v}}, v < V. \) This Markov model is often used in the stochastic resonance framework (see for instance [17]). Here we can compute explicitly the invariant measure (see also [17] Proposition 4.1.2 p.34)

Lemma 3.1. The periodic stationary probability measure PSPM is given by:

\[ \mu_1(t) = \frac{e^{-(\varphi_0 + \varphi_1)t}}{1 + e^{-(\varphi_0 + \varphi_1)t/2}} \frac{\varphi_0 - \varphi_1}{\varphi_0 + \varphi_1} + \frac{\varphi_1}{\varphi_0 + \varphi_1} \]  

(3.2)

and \( \mu_1(t) + \mu_2(t) = 1, \mu_1(t + T/2) = \mu_2(t), \mu_2(t + T/2) = \mu_1(t). \) Here \( \mu_1 \) (resp. \( \mu_2 \)) stands for \( \mu_{s_1} \) (resp. \( \mu_{s_2} \)).

Proof. Using the description of the PSPM in Proposition 1.3 we obtain

\[ \mu_1(t) = \mu_1(0) e^{-(\varphi_0 + \varphi_1)t} + \frac{\varphi_1}{\varphi_0 + \varphi_1} \left( 1 - e^{-(\varphi_0 + \varphi_1)t} \right) \]

\[ = \left( \mu_1(0) - \frac{\varphi_1}{\varphi_0 + \varphi_1} \right) e^{-(\varphi_0 + \varphi_1)t} + \frac{\varphi_1}{\varphi_0 + \varphi_1}, \quad 0 \leq t < T/2. \]

(3.3)

Furthermore, by symmetry arguments, the dynamics of the periodic invariant measure satisfies: \( \mu_1(t + T/2) = \mu_2(t) \) for all \( t \geq 0. \) We deduce in particular that \( \mu_1(T/2) = \mu_2(0) = 1 - \mu_1(0). \) Thus

\[ \mu_1(0) = \frac{\varphi_0 + \varphi_1 e^{-(\varphi_0 + \varphi_1)T/2}}{(\varphi_0 + \varphi_1)(1 + e^{-(\varphi_0 + \varphi_1)T/2})}. \]

The equation (3.3) then permits to conclude.

An immediate consequence of Corollary 2.3 leads to the explicit computation of the mean number of transitions (the details of the proof are left to the reader).

Proposition 3.2. The mean number of transitions from state \( s_1 \) to state \( s_2 \) of the periodically driven Markov chain satisfies

\[ \lim_{n \to \infty} \frac{1}{n} \mathbb{E}[N_{nT}] = \frac{\varphi_0 \varphi_1 T}{\varphi_0 + \varphi_1} + \left( \frac{\varphi_0 - \varphi_1}{\varphi_0 + \varphi_1} \right)^2 \tanh \left( \frac{(\varphi_0 + \varphi_1)T}{4} \right). \]

(3.4)

This expression represents the asymptotic averaged number of one-sided transitions between one period.
We are interested in the phenomenon of stochastic resonance associated to continuous-time process \((X_t, t \geq 0)\). This process essentially depends on two parameters: a parameter \(\epsilon\) describing the intensity of the transition rates between both states \(\{s_1, s_2\}\) (some small \(\epsilon\) corresponds to a frozen situation: the Markov chain remains in the same state for a long while) and a second parameter \(T\), the period of the process dynamics. By considering the normalized process \(Y_t = X_{\epsilon T}\), especially its paths on a fixed interval \([0, S]\), we observe the following phenomenon (for fixed \(\epsilon\)): if \(T\) is small then there are very few transitions of \(Y\): the process tends to remain in its original state. If \(T\) is large, \(Y\) behaves in a chaotic way: lots of transitions are observed. For some intermediate values of \(T\), the random paths of \(Y\) are close to deterministic periodic functions (one transition in each direction per period). Let us note that this phenomenon can also be observed by freezing the period length \(T\) and varying the intensity \(\epsilon\) of the rates.

The aim is therefore to point out the best relationship (tuning) between \(\epsilon\) and \(T\) which makes the process \(Y\) the most periodic as possible. If the process is close to a periodic function then the mean number of transition from state \(s_1\) to state \(s_2\) is close to \(1\) per period. By Proposition 3.2, it is then sufficient to find the best relation between \(\epsilon\) and \(T\) such that

\[
\mathbb{E}_\mu[N_T] = 1. \quad (3.5)
\]

In Figure 3.1, we set \(\epsilon = 0.1, V = 2, v = 1, p = q = 1\) and let \(T\) vary.

Figure 1: Average number of transitions

We can clearly observe that there is one and only one period corresponding to the condition (3.5).

**Proposition 3.3.** Let \(T^*\) be the period which provides an average number of transitions per period equal to \(1\). The following asymptotic behaviour holds, as \(\epsilon\) tends to 0,

\[
T^*_\epsilon \sim \frac{V - v}{2q\epsilon} e^{v/\epsilon}. \quad (3.6)
\]

**Proof.** The condition (3.5) combined with Proposition 3.2 leads to the equation

\[
\frac{\varphi_0\varphi_1 T}{\varphi_0 + \varphi_1} + \left(\frac{\varphi_0 - \varphi_1}{\varphi_0 + \varphi_1}\right)^2 \tanh\left(\frac{(\varphi_0 + \varphi_1)T}{4}\right) = 1.
\]

The aim is to solve it and let \(\epsilon\) tend to 0. The left member in the previous equation is an increasing function of \(T\). We introduce the change of variable \(U^\epsilon = (\varphi_0 + \varphi_1)T/4\). We first prove that \(U^\epsilon\) increases as \(\epsilon\) decreases. \(U^\epsilon\) satisfies \(K(U^\epsilon, \epsilon) = 1\) with

\[
K(U^\epsilon, \epsilon) = \frac{4\varphi_0\varphi_1 U^\epsilon}{(\varphi_0 + \varphi_1)^2} + \left(\frac{\varphi_0 - \varphi_1}{\varphi_0 + \varphi_1}\right)^2 \tanh(U^\epsilon).
\]

Both functions \(\epsilon \mapsto K(\cdot, \epsilon)\) and \(x \mapsto K(x, \cdot)\) decrease for \(\epsilon\) small and \(x\) large enough. It follows that \(U^\epsilon\) increases when \(\epsilon\) decreases and tends to 0. Let us
assume $U^\epsilon \to U_0 < \infty$ in the limit $\epsilon \to 0$. Then $K(U^\epsilon, \epsilon) \to \tanh(U_0)$ which contradicts the identity $K(U^\epsilon, \epsilon) = 1$. We deduce that $U^\epsilon \to \infty$ when $\epsilon \to 0$. Now let us set $t = e^{-V/\epsilon}$ and $\beta = v/V < 1$. With these new parameters $K$ can be written like

$$1 = \tilde{K}(U, t) = \frac{4pqt^{1+\beta}U^\epsilon}{(pt + qt^\beta)^2} + \left( \frac{pt - qt^\beta}{pt + qt^\beta} \right)^2 \tanh(U^\epsilon).$$

Let us define $\tanh(U^\epsilon) = 1 - W$ then $U^\epsilon = \frac{1}{2} \log \left( \frac{2W}{V} \right)$, we obtain that $W$ tends to 0 when $t \to 0$ and the previous equation becomes:

$$1 = \tilde{K}(W, t) = \frac{4pqt^{1+\beta}}{(pt + qt^\beta)^2} \log \left( \frac{2W}{V} \right) + \left( \frac{pt - qt^\beta}{pt + qt^\beta} \right)^2 (1 - W).$$

Thus, when $t \to 0$, we have

$$\tilde{K}(W, t) - 1 = \left( \frac{-2pqt^{1+\beta}}{(pt + qt^\beta)^2} \log W + o(\log W) \right) + (1 - \frac{4p}{q}t^{1-\beta} + o(t^{1-\beta}))(1 - W) - 1$$

$$= \frac{-2pqt^{1+\beta}}{(pt + qt^\beta)^2} \log W - W + o(t^{1-\beta} \log W) = 0.$$

If $W = r_0 t^\alpha \log(t) R(t)$ with $\alpha = 1 - \beta$ and $r_0 = -\frac{2p}{q} \beta = -\frac{2p}{q}(1 - \beta)$, we obtain the limit $R(t) \to 1$ when $t \to 0$ and therefore

$$U^\epsilon \sim -\frac{1}{2} \log \left( \frac{2p}{q} (1 - \beta) t^{1-\beta} (-\log t) \right) \sim -\frac{1 - \beta}{2} \log t \sim \frac{(1 - \beta)V}{2\epsilon} = \frac{V - v}{2\epsilon}.$$

We recall $U^\epsilon = (\varphi_0 + \varphi_1)T/4$ which leads to the result set.

In [17], several quality measures have been proposed to point out the optimal tuning of $Y$: the spectral power amplification (SPA), the SPA to noise intensity ratio (SPN), the energy (En), the energy to noise intensity ratio (ENR), the out-of-phase measure which describes the time spent in the most attractive state, the entropy or relative entropy. In his PhD report, I. Pavlyukevich computes for each measure the optimal relation between $\epsilon$ and $T^\epsilon_{\text{mes}}$, the length of the period, in the small $\epsilon$ limit, we adopt a similar procedure in Proposition 3.3. So we can now gather these quality measures into three families:

- for the first family, the optimal tuning satisfies $T^\epsilon_{\text{mes}} = o(T^\epsilon_{\text{opt}})$ where $T^\epsilon_{\text{opt}}$ is given by (3.6). The associated Markov chain has an average number of transitions from $-1$ to $+1$ strictly smaller than 1. This family contains in particular the SPN.

- The second family concerns $T^\epsilon_{\text{opt}} = o(T^\epsilon_{\text{mes}})$. The Markov chain has then more than one transition per period on average. This family contains most of the measures: SPA, En, Out-of-phase, the entropy and relative entropy.

- Finally in the third family $T^\epsilon_{\text{opt}}$ and $T^\epsilon_{\text{mes}}$ are comparable, this is namely the case for ENR.
3.2 Infinitesimal generator with constant trace

Let us finally present a second example of periodic forcing in the stochastic resonance framework. This model was introduced by Eckmann and Thomas [7]. The aim in this paragraph is to find the optimal tuning between the noise intensity in the system and the period length in order to reach an average number of transitions during one period close to 1. This approach is different from the study presented in [7].

The model consists in a continuous-time Markov chain with periodic forcing: the transition rates are given by

$$\varphi_{1,2}(t) = \epsilon(a + \cos \omega t) \quad \text{and} \quad \varphi_{2,1}(t) = \epsilon(a - \cos \omega t), \quad a > 1. \quad (3.7)$$

The period satisfies $T = (2\pi)/\omega$. In this particular case, the trace of the infinitesimal generator, defined by (0.1), is a constant function. It is then quite simple to compute explicitly the periodic stationary probability measure and the mean number of transition.

**Lemma 3.4.** The periodic stationary probability measure of the periodic forced Markov chain is given by

$$\mu_1(t) = \frac{1}{2} \frac{\epsilon}{4\epsilon^2 a^2 + \omega^2} (2\epsilon a \cos \omega t + \omega \sin \omega t). \quad (3.8)$$

**Proof.** Using Proposition 1.3, we obtain

$$\mu_1(t) = \mu_1(0) e^{-2\epsilon a t} \int_0^t \left( \epsilon a - \epsilon \cos \omega s \right) e^{-2\epsilon a (t-s)} ds.$$ 

Hence

$$\mu_1(t) = \mu_1(0) e^{-2\epsilon a t} + \frac{1 - e^{-2\epsilon a t}}{2} + \frac{2\epsilon^3 a e^{-2\epsilon a t} - 2\epsilon^2 a \cos \omega t - \omega \epsilon \sin \omega t}{4\epsilon^2 a^2 + \omega^2}.$$ 

Setting $\mu_1(T) = \mu_1(0)$, we obtain $\mu_1(0) = \frac{1}{2} - \frac{2\epsilon^2 a}{4\epsilon^2 a^2 + \omega^2}$ and consequently the announced statement. \hfill \Box

An application of Corollary 2.3 permits to describe the large time asymptotics for the first moments of the transitions from state $s_1$ to state $s_2$. It suffices to compute explicitly $\int_0^T \varphi_{1,2}(t) \mu_1(t) dt$. The result is described in the following statement while the proof is left to the reader.

**Proposition 3.5.** The mean number of transition per period is equal to

$$\lim_{n \to \infty} \frac{1}{n} \mathbb{E}_\mu[N_{nT}] = \frac{\epsilon a T}{2} - \frac{\epsilon^3 a T}{4\epsilon^2 a^2 + \omega^2}. \quad (3.9)$$

and $\mu$ given by (3.8).

Let us now discuss the suitable choice of the period such that $\mathbb{E}_\mu[N_T] = 1$. We then need to solve

$$\pi \epsilon a (4\epsilon^2 a^2 + \omega^2) - 2\pi \epsilon^3 a = \omega (4\epsilon^2 a^2 + \omega^2). \quad (3.10)$$
It is obvious that $\omega$ is of the order $\epsilon$, we set $\omega = \mu \epsilon$ and look for the best choice of the parameter $\mu$. Considering (3.10), the optimal value $\mu$ is in fact a real root of the following polynomial function

$$P(\mu) := \mu^3 - \pi a \mu^2 + 4a^2 \mu + 2\pi a (1 - 2a^2)$$

It is straightforward to prove that this polynomial function has a single positive root since it is increasing and verifies $P(0) < 0$. Using the Cardan formula, we can obtain an explicit expression of $\mu_{optimal}$ which depends of course on the coefficient $a$, this dependence is asymptotically linear as $a$ becomes large.

Acknowledgements

We are very grateful to Mihai Gradinaru for interesting conceptual and scientific discussions on the problem of stochastic resonance associated to the two-states Markov chain. His availability was greatly appreciated.
