Abstract—In this paper, we present a joint blind channel estimation and symbol detection for decoding a blurred and noisy 1D barcode captured image. From an information transmission point of view, we show that the channel impulse response, the noise power and the symbols can be efficiently estimated by taking into account the signal structure such as the cyclostationary property of the hidden Markov process to estimate. Based on the Expectation-Maximisation method, we show that the new algorithm offers significative performance gain compared to classical ones pushing back the frontiers of the barcode technology.

I. INTRODUCTION

Barcode is an essential element of electronic data interchange. Since its birth in 1948, this technology is continuously growing up. Its success comes from the simplicity of the binary data representation and the efficiency of the reading device in a controlled acquisition environment. Originally, barcodes represent data through the width and the spacing of parallel lines, and may be referred to as 1D barcodes. Binary data can also be depicted in geometric patterns such as dots or squares within images known as 2D barcodes.

When shot, the original barcode is degraded by blur caused by a bad focalisation and/or a camera movement, in addition to noise, the whole resulting in a blurred noisy received signal, Fig.1. In fact, two main types of blur can affect the received signal; the optical blur owing to bad focus and diffraction phenomena and the motion blur coming from the camera mobility with respect to the barcode. Many models have been proposed for these two kinds of blur such as parametric models [10], Gaussian models [4] and models based on the global transfer function [3] and [7].

In the scientific literature few works are related to 1D and 2D barcode coding. Pavlidis et al. [13] have published a study related to information theory fundamentals outlining the process for barcode design using error detection and correction techniques. Tsi et al. [14] have developed a method that allows the calculation of the working range in case of a CCD-based reader. Houni et al [8] have studied the performance in the framework of the information theory and they have proposed two new measures: the theoretical depth of field and the theoretical resolution. In [11], a method of reading linear barcodes using the Hough transform is proposed. The algorithm is designed to a particular type of barcode (Code39). Recently Ould Barikalla et al [12] have proposed a 2D barcode decoder using an iterative structure based on a factor graph representation. In all these works, decoders take into account the prior knowledge of the channel at the receiver. In practice,

a training sequence enables the channel to be estimated but the estimation error leads to performance degradation of the decoder.

In this paper, we consider the decoding problem of barcode without training sequence. In particular, we propose a blind decoder that jointly estimates the channel and the symbols. This joint channel estimation and symbol detection can be performed, using probabilistic algorithm based on maximum likelihood criterion [1], [5], [6] and [9]. Here, we show that the channel state of a barcode is a cyclostationary process and we propose a new joint channel estimator and symbol detector based on the Expectation Maximisation algorithm which takes advantage of this property. By exploiting the cyclostationarity property, the number of paths of the channel state in the lattice diagram is reduced. As a consequence, the detector is more robust to noise and the detector performances are significantly improved.

The paper is organised as follow. In Section 2, both the barcode and the channel are modeled respectively, by a cyclostationary process and by a finite impulse response filter with an additive white Gaussian noise. Section 3 describes the Expectation - Maximisation algorithm used for the channel estimation. Section 4 is focused on the symbol detection. Section 5 presents the results of a simulation study that has been conducted to assess the new algorithm's performance. Conclusions are given in Section 6.

Fig. 1: Original and blurred barcode

Notation

$\lfloor x \rfloor$ returns the smallest integer value greater than or equal to x . $x(i : j) = (x_i, x_{i+1}, \dots, x_j)$. x^T is the classical matrix transpose.

II. SYSTEM MODEL

Let $x'_0, x'_1, \dots, x'_{N-1}$ be a sequence of N bits to transmit. Each bit is represented by a bar of width r_x . So the barcode is given by $x_k = x'_{\lfloor \frac{k}{r_x} \rfloor}$, $k \in \{0, \dots, K-1\}$ with $K = Nr_x$.

When shot, the barcode is degraded by a blur coming from both the optical block and the movement of the camera which are modeled by a finite impulse response filter of length L . Besides, an additive white Gaussian noise takes into account the residual stochastic imperfections. Using matrix notation, the observed sequence $Y = (y_0 \dots y_{K-1})^T$ is given by:

$$y_k = H^T X_k + w_k \quad \forall k \in \{0, \dots, K-1\} \quad (1)$$

where $H = (h_0 \dots h_{L-1})^T$ is the channel coefficients vector, H is symmetric and decreasing from central maximum. Indeed, the blur is the result of the bad focalisation and the camera motion, which belongs to the class of this symmetric blur [3], [4], [10] and [7].

$X_k = (x_k \dots x_{k-L+1})^T$ is the displayed symbol vector and w_k is an additive white Gaussian noise with variance σ^2 . X_k verifies the equation :

$$X_k = B X_{k-1} + V_k \quad (2)$$

With $B = \begin{pmatrix} 0 & 0 & \dots & 0 \\ 1 & \ddots & & \vdots \\ \vdots & & \ddots & 0 \\ 0 & \dots & 1 & 0 \end{pmatrix}$ and $V_k = (x_k 0 \dots 0)^T$.

From (2), we deduce that X_k is a Markovian process which belongs to a set $\{\xi^{0,r_x}, \dots, \xi^{M-1,r_x}\}$ in which the cardinal number M and the states are relied to both the channel length L and the bar width r_x . Specifically, the number of states M follows the equation :

$$M = \begin{cases} 2L & \text{if } L \leq r_x \\ \sum_{i=0}^{r_x-1} 2^{(1+\lfloor (L-1)/r_x \rfloor)} - 2(r_x - 1) & \text{otherwise} \end{cases} \quad (3)$$

Let's point out from equation (3) that M is decreasing with r_x which is an interesting property when dealing with the recovery of the information carried by the barcode. The distance between the various states becomes larger so that detection is less sensitive to the noise.

By denoting $A_k = (a_{mn}(k))_{0 \leq m, n \leq M-1}$, the transition matrix of X_k is given by :

$$a_{mn}(k) = P(X_k = \xi^{n,r_x} | X_{k-1} = \xi^{m,r_x}) \quad (4)$$

$$= \begin{cases} \frac{1}{2} \delta(\xi^{n,r_x}(1:L-1) - \xi^{m,r_x}(0:L-2)) & \text{if } \frac{k-1}{r_x} \in \mathbb{N} \\ \delta(\xi^{n,r_x}(1:L-1) - \xi^{m,r_x}(0:L-2)) & \text{otherwise} \end{cases}$$

with $\delta(\cdot)$ the Kronecker symbol. As shown in equation (4), if X_k is at the border of the bar, two transitions are possible, otherwise only one transition is allowed.

From equation (1) and the Markovian properties of $X = (X_0 \dots X_{K-1})$, we deduce the distribution of (X, Y) :

$$P_\theta(Y, X) = P(X_0) \prod_{k=1}^{K-1} P(X_k | X_{k-1}) \prod_{k=0}^{K-1} f_{Y_k | X_k, \theta}(y_k) \quad (5)$$

where $f_{Y_k | X_k, \theta}(y_k) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp -\frac{1}{2} \left(\frac{y_k - H^T X_k}{\sigma} \right)^2$, $P(X_k | X_{k-1})$ is given by equation (4) and $\theta = (H, \sigma^2, r_x)^T$

is the parameter vector of the model.

From the described model, X_k can be represented in a trellis diagram. Since the Markov process is cyclostationary, the lattice is cyclic so that the number of paths is reduced. As a consequence, the detection of the optimal sequence is simplified and more robust to noise.

III. PARAMETER ESTIMATION

A. EM algorithm

The maximum likelihood of θ is given by :

$$\hat{\theta} = \arg \max_{\theta} f_{Y, \theta}(y) \quad (6)$$

where $f_{Y, \theta}$ is the likelihood of the observation. Nevertheless in our application the likelihood maximisation is not tractable. On the other hand, when considering the complete data (X, Y) , the maximum likelihood estimation can be closely approximated by the Expectation-Maximisation algorithm (EM). This recursive algorithm consists of an iterative maximization of the auxilliary function $Q(\theta, \theta^{(i-1)})$.

At the i^{eme} iteration, the two following steps are performed: E step

$$Q(\theta, \theta^{(i-1)}) = E_{X|Y, \theta^{(i-1)}} [\log(P_\theta(X, Y))] \quad (7)$$

M step

$$\theta^{(i)} = \arg \max_{\theta} Q(\theta, \theta^{(i-1)}) \quad (8)$$

In order to proceed to the estimation of the three components of θ , Q is first maximised with regards to (H, σ^2) and the result is maximised relatively to the width r_x .

$$\max_{\theta} Q(\theta, \theta^{(i-1)}) = \max_{r_x} \max_{H, \sigma^2} Q(\theta, \theta^{(i-1)}) \quad (9)$$

When considering the special case where the width $r_x = 1$, X_k is a stationary Markov process and the estimation algorithm of (H, σ^2) has been proposed by Kaleb et al. [9]. In general case, i.e. whatever the value of r_x , we show that the channel coefficients and the noise variance estimates are respectively given by these two equations:

$$\left\{ \sum_{k=0}^{K-1} \sum_{m=0}^{M-1} P_{\theta^{(i)}}(X_k = \xi^{m,r_x} | Y) \xi^{m,r_x T} \xi^{m,r_x} \right\} H_{r_x}^{(i+1)} = \sum_{k=0}^{K-1} \sum_{m=0}^{M-1} P_{\theta^{(i)}}(X_k = \xi^{m,r_x} | Y) y_k \xi^{m,r_x T} \quad (10)$$

and

$$\sigma_{r_x}^{2(i+1)} = \frac{1}{K} \sum_{k=0}^{K-1} \sum_{m=0}^{M-1} P_{\theta^{(i)}}(X_k = \xi^{m,r_x} | Y) \times |y_k - H_{r_x}^{(i+1)} \xi^{m,r_x}|^2 \quad (11)$$

where $P_{\theta^{(i)}}(X_k = \xi^{m,r_x} | Y)$ is obtained by the forward backward algorithm [2].

We propose to consider the estimation of the width r_x as well as the estimation of the channel impulse response. Moreover, the cyclostationarity of X_k is exploited to optimise the accuracy of the estimates.

B. Joint estimation of H and σ^2 given r_x

For a given r_x , the estimates of H_{r_x} and $\sigma_{r_x}^2$ are obtained by solving the equations (10) and (11), where the marginal posterior probability $P_{\theta^{(i)}}(X_k = \xi^{m,r_x}|Y)$ is recursively calculated by the forward backward algorithm adapted to the cyclostationarity of the hidden process X_k . When $r_x > 1$, the algorithm chooses the optimal sequence in a reduced set of paths in the lattice diagram, since some transitions are not possible.

Let us note

$$\gamma_m(k) = P_{\theta}(X_k = \xi^{m,r_x}|Y) \quad (12)$$

$\forall m \in \{0, \dots, M-1\} \forall k \in \{0, \dots, K-1\}$, the marginal posterior distribution of X_k . One shows that :

$$\gamma_m(k) = \frac{\alpha_m(k) \beta_m(k)}{\sum_{n=0}^{M-1} \alpha_n(k) \beta_n(k)} \quad (13)$$

where $\alpha_n(k)$ and $\beta_n(k)$ are respectively the forward and the backward probabilities defined as follow :

$$\alpha_m(k) = P_{\theta}(Y_1 = y_0, \dots, Y_k = y_k, X_k = \xi^{m,r_x}) \quad (14)$$

$$\beta_m(k) = P_{\theta}(Y_{k+1} = y_{k+1}, \dots, Y_{K-1} = y_{K-1} | X_k = \xi^{m,r_x}) \quad (15)$$

These probabilities can be calculated recursively by :

$$\alpha_m(k+1) = [\sum_{n=0}^{M-1} \alpha_n(k) a_{nm}(k)] f_m(y_{k+1}) \quad (16)$$

$$\beta_m(k) = \sum_{n=0}^{M-1} \beta_n(k+1) a_{mn}(k) f_n(y_{k+1}) \quad (17)$$

where

- $f_n(y_k)$ is the density probability function of Y given $X_k = \xi^{n,r_x}$. From equation (1), the Gaussian density with mean ξ^{n,r_x} and variance σ^2 is deduced.
- $a_{mn}(k)$ is the transition probability (4).

The initialisation step of the forward and the backward algorithm are:

$$\alpha_m(1) = \pi_m f_m(y_0) \text{ and } \beta_m(K) = 1, \forall m \in \{0, \dots, M-1\}$$

C. Estimation of r_x

r_x is estimated using the maximum likelihood criterion

$$\hat{r}_x = \arg \max_{r_x} (g(H_{r_x}, \sigma_{r_x}^2, r_x)) \quad (18)$$

with g is the pseudo likelihood

$$g(H_{r_x}, \sigma_{r_x}^2, r_x) = \max_{H, \sigma^2} Q(\theta, \theta^{(i-1)}) \quad (19)$$

H_{r_x} and $\sigma_{r_x}^2$ are the estimates obtained using equations (10) and (11). Maximisation of g with regard to r_x is equivalent to maximisation of the likelihood. Since, explicit expression of the estimator $\hat{r}_x$ can not be identified, g is calculated for all possible value of $r_x \in \{1, \dots, K-1\}$. Next, we choose $(\hat{H}_{r_x}, \hat{\sigma}_{r_x}^2, \hat{r}_x)$ that gives the highest likelihood.

IV. SYMBOL DETECTION

The optimal decision on symbol is obtained using the Marginalised Posterior Mode (MPM) criterion, which is based on the maximisation of the marginal posterior probability. For symbol x'_k from the transmitted sequence of length N , the decision is taken by:

$$P_{\theta}(x'_k = 0|Y) \underset{\hat{x}'_k=0}{\gtrless} P_{\theta}(x'_k = 1|Y) \quad (20)$$

Let Ω^j be the set of realisations $\xi = (\xi^0, \dots, \xi^{r_x-1})$ of $X_{kr_x:(k+1)r_x-1}$ such as $x'_k = j$. Since, there is a one to one relation between x'_k and $X_{kr_x:(k+1)r_x-1}$

$$P_{\theta}(x'_k = j|Y) = P_{\theta}(X_{kr_x:(k+1)r_x-1} \in \Omega^j|Y) \quad (21)$$

With,

$$P_{\theta}(X_{kr_x:(k+1)r_x-1} \in \Omega^j|Y) = \sum_{\xi \in \Omega^j} P_{\theta}(X_k = \xi^0|Y) \times$$

$$\prod_{l=1}^{l=r_x-1} P(X_{k+l} = \xi^{l+1} | X_{k+l-1} = \xi^l) \quad (22)$$

Where, $P_{\theta}(X_k = \xi^0|Y)$ is obtained by the forward backward algorithm (III-B) and the transition probabilities are given by equation (4). This criterion takes into account the structure of the barcode signal, via the marginal probability and the transition probability matrix.

V. JOINT CHANNEL AND RESOLUTION ESTIMATION ALGORITHM

From, subsections (III-A), (III-B), (III-C) and (IV), we deduce the algorithm to joint channel and barcode resolution estimation and symbol detection (CRESO):

Algorithm 1 Joint channel and resolution estimation and symbol detection algorithm

- 1: **for** $r_x = 1, \dots, K-1$ **do**
 - 2: Calculate the number of state and the transition probability matrix using equations (3) and (4).
 - 3: Initialisation, $H^{(0)}, (\sigma^2)^{(0)}$.
We denote by ε a predetermined threshold
 - 4: **while** $|H_{r_x}^k - H_{r_x}^{k+1}| > \varepsilon$ **do**
 - 5: Calculate the marginal posterior probability using equations (16), (17) and (13).
 - 6: Estimation of H_{r_x} and $\sigma_{r_x}^2$ from (10) and (11).
 - 7: **end while**
 - 8: Given H_{r_x} and $\sigma_{r_x}^2$, calculate the pseudo likelihood using equation (19).
 - 9: **end for**
 - 10: Select the parameter $\hat{\theta} = \{\hat{H}_{r_x}, \hat{\sigma}_{r_x}^2, \hat{r}_x\}$ that maximises the pseudo likelihood (19).
 - 11: Detection of symbol using equations (20), (21) and (22).
-

VI. SIMULATIONS RESULTS

In this section, the performance of the proposed algorithm is illustrated through numerical simulations.

Fig. 2: Blurred signal with blur length $L=10$, $r_x = 3$ and $N = 100$

Fig.2 shows the observed signal degraded by blur and noise distortion versus the initial transmitted signal. It confirms that the received signal can not be directly decoded. Indeed, a joint blur identification and symbol detection algorithm is required to efficiently recover the original signal.

In the following, a set of binary symbol $\{0,1\}$ have been considered and the results have been obtained with $N_s = 1000$ Monte Carlo runs. For each run, a new sequence of length $N = 100$ has been generated with a barcode resolution barcode $r_x = 3$ and a new simulated channel of length $L = 3$, the threshold $\varepsilon = 10^{-5}$.

To analyse the performances of the proposed algorithm, we consider three cases:

- The Kaleb's algorithm [9], constructed without exploiting the cyclostationarity of the hidden Markov process.
- The CRES algorithm, described in Algorithm 1.
- A simple algorithm which does not take into account the channel model (1), but assumes known the resolution. The decision rule is:

$$\left(\frac{1}{r_x} \sum_{i=k r_x}^{(k+1)r_x} y_i \right) \begin{matrix} \hat{x}'_k=0 \\ \hat{x}'_k=1 \end{matrix} \begin{matrix} \leq \\ \geq \end{matrix} \frac{1}{2} \quad (23)$$

$$\forall k \in \{0, \dots, N-1\}$$

In the experiments, E_b/N_0 is the energy per bit to noise power spectral density ratio, with energy per bit defined as:

$$E_b = r_x H^T E [X_k X_k^T] H \quad (24)$$

Estimation of the resolution r_x

Table (I) illustrates the performance of estimation of r_x . We calculate for different value of r_x the error rate defined as $\rho = \frac{n_b}{N_s}$, where n_b is the number of false detection and N_s the number of trials. As shown in Table (I) the error rate decreases rapidly, with E_b/N_0 . In fact, the error rate is due to noise distortion and interference intersymbol. The later, related

$r_x \backslash \frac{E_b}{N_0}$	2dB	4dB	6dB	8dB	10dB
$r_x=2$	0.218	0.032	0.008	0.002	0.001
$r_x=3$	0.169	0.019	0.002	0.001	0
$r_x=4$	0.083	0.005	0	0	0
$r_x=5$	0.057	0.006	0	0	0

TABLE I: r_x error rate for channel length $L = 3$ and block length $N = 100$

to r_x/L , is reduced when $r_x/L > 1$. Obviously, for the same value of E_b/N_0 , estimation performance is better for $r_x/L > 1$.

Channel estimation

The Root Mean Squared Error (RMSE), assessing the quality of the estimation of the channel, is defined as:

$$RMSE = \sqrt{\frac{(H - \hat{H})^T (H - \hat{H})}{H^T H}}$$

With H and $\hat{H}$ are respectively the true channel coefficients vector and the estimated one.

Fig. 3: RMSE vs E_b/N_0 , for $N=100$, $L=3$ and $r_x = 3$

Fig.3 shows the superiority of CRES algorithm, in term of RMSE. This clearly illustrates the benefit of exploiting the cyclostationarity of the hidden Markov process in the trellis diagram. This leads to a more accurate estimation of the marginal posterior probability, which directly impacts the channel estimation equation(10). Besides, when the barcode resolution r_x is estimated, the RMSE is larger for $E_b/N_0 < 4dB$, but becomes identical to the one when r_x is known for $E_b/N_0 \geq 4dB$.

For the estimation of the noise variance, we note the same behavior. The $RMSE = 6.7710^{-2}$ for the CRES algorithm and it is equal to the double for the Kaleb's one $RMSE = 13.0510^{-2}$, for $E_b/N_0 = 5dB$. Indeed, as channel coefficients, the estimation of the noise variance depends on the marginal posterior probability equation(11) which takes into account the true sequence structure of the barcode.

Now, the rapidity of convergence of the estimation is assessed. Fig.4 shows that the CRES is both more accurate and faster than the Kaleb's one. In this exemple,the convergence has

been achieved at the 4th iteration, while the Kaleh's algorithm requires twice as much iterations.

Fig. 4: Evolution of the RMSE with iterations, with $L = 3$, $r_x = 3$ and $N = 100$

Symbol detection

Fig. 5: BER performance for known and estimated r_x , $L=3$, $r_x = 3$, $N = 100$

Fig. 5 illustrates Bit Error Rate (BER) performance, curves with solid and dashed line correspond respectively to the CRES algorithm and Kaleh's method. When r_x is known, we note that BER performance is significantly improved using CRES algorithm, and this performance gain increases with E_b/N_0 . This result is explained by the fact that, with the CRES algorithm, decision is taken in a trellis diagram constructed with respect of the original signal structure.

When r_x is estimated, the resolution and channel estimation error lead to an increase of the BER for $E_b/N_0 < 4\text{dB}$ for the CRES algorithm. For the Kaleh's one, r_x is supposed to be known. Nevertheless, the CRES algorithm still performs better for $E_b/N_0 > 4\text{dB}$, and the estimation of r_x does not really degrades the overall performance. For $E_b/N_0 > 4\text{dB}$, the curve obtained with and without estimation of r_x are the same.

On the other hand, the poor performances of the method based on the decision without channel estimation confirms the need of a more accurate algorithm to ensure correct reconstruction of the original signal.

VII. CONCLUSION

In this paper, we have proposed a blind channel estimation and symbol detection algorithm. Blur identification has been performed using the EM algorithm. Besides, given that the received signal is modeled as a hidden Markov chain, a version of the forward-backward algorithm, suitable to the cyclostationarity of the Markov process, has been proposed to estimate the marginal posterior probability. We have shown that, when the barcode structure is taken into account in the lattice, the estimation of the marginal posterior probability is easier and more accurate. This advantage directly impacts both the channel estimation and the symbol detection. Simulation results show a fast convergence, a large gain for the parameter estimation and a smaller symbol error rate compared to existing approaches. As a consequence, the CRES algorithm can be efficiently used with larger intersymbol interference, thus enabling to read more compact barcode and to allow higher mobility between the barcode and the camera.
