HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
I. INTRODUCTION

One of the most striking manifestation of macroscopic quantum coherence is the Josephson effect: a DC current flows when a phase difference is imposed on a junction bridging two superconductors with a narrow insulating, metallic or semiconducting region. When applying a constant voltage bias to this same junction, an oscillatory current arises and the application of an rf-irradiation leads to the observation of Shapiro steps with zero differential resistance and phase coherence. More generally, the microscopic origin of these effects is Andreev reflections of electrons and holes at the boundaries of the two superconductors. The same mechanism participates in the appearance of a subgap structure in highly transparent voltage-biased junctions, a feature understood to be due to dissipative quasiparticle emissions called multiple Andreev reflections (MAR), which were observed in atomic point contact experiments.

Non-local quantum mechanical phenomena and entanglement are nowadays investigated in condensed matter physics, in particular in superconducting circuits. Multiterminal superconducting hybrid devices with one superconducting arm and two normal metal electrodes have also been studied in the last decade with the aim of detecting non-local entangled electron pairs. There is now convincing experimental data on non-local current and noise detection which points in this direction. Yet, there is also a growing interest in three-terminal all-superconducting hybrid structures, so far mainly in regimes dominated by phase-insensitive processes. A recent calculation for a SNS junction, where the N region is tunnel-coupled to another superconductor, also showed resonances ascribed to voltage-induced Shapiro steps.

The present work shows that a non-dissipative phase-coherent Josephson signal of Cooper pair transport could be observed in a device consisting of three superconductors driven out of equilibrium. This effect relies on a combination of both direct Andreev reflections and non-local crossed Andreev reflections (CAR), and is thus directly tied to non-local entangled electron processes as well as Josephson physics. Here, the “bijunction” which we propose consists of a central superconductor $S_0$ coupled via two adjustable quantum dots to two lateral superconductors $S_a$ and $S_b$, biased at voltages $V_a$ and $V_b$ (Fig. 1). As the coherence length of $S_0$ (which is grounded at $V_0 \equiv 0$) is assumed to be larger than the distance between the dots, this bijunction cannot be simply considered as two separated junctions in parallel. Each junction consists of a quantum dot, made with e.g. carbon nanotubes or nanowires, and labeled $D_{\alpha}$ ($\alpha = a, b$). The dots introduce additional degrees of freedom (position of energy levels, coupling widths) which provide full control of the junctions. Equilibrium calculations in a similar three-terminal device involving normal-metal interfaces showed that a bijunction could be a source of spatially correlated pairs of Cooper pairs (referred to as “non-local quartets”) transmitted into $S_a$ and $S_b$ simultaneously.

This article reports on calculations of out-of-equilibrium transport in a biased $S_aD_{\alpha}S_0D_{\beta}S_b$ bijunction, with as main results:

(i) At commensurate voltages $nV_a + mV_b = 0$ ($m$ and $n$ integers), DC Josephson resonances appear, which correspond to the phase-coherent transport of $n$ pairs to $S_a$ and $m$ pairs to $S_b$, from $S_0$.

(ii) The Josephson current-phase relation of quartet resonances ($n = m = 1$) and that of some higher-order resonances are $\pi$-shifted at low bias. This new mechanism for producing a $\pi$-shift is of particular importance.
(iii) Gate and/or bias voltages can be tuned to enhance the multipair resonances by orders of magnitude as compared to the adiabatic regime, making them easily observable in experiments.

(iv) At larger biases, a DC quasiparticle-pair interference term, corresponding to phase-dependent MAR, emerges from the dissipative Josephson component.

The structure of this article is the following. In Sec. II, we explain qualitatively the multi-pair Josephson resonances from a simple adiabatic argument. The following sections are concerned with an exact out-of-equilibrium calculation, valid at arbitrary voltages. Sec. III discusses results obtained in the regime where the quantum dots have a behavior similar to metallic junctions. The next section shows results for the opposite regime where the dots present a narrow resonance. Finally, Sec. VI presents the conclusions and perspectives of this work.

II. ADIABATIC ARGUMENT

A simple phase argument suggests the existence of quartet resonances in a bijunction. Starting with an equilibrium situation, the current-phase relation of a single tunnel junction $S_aS_0$ with phases $\varphi_a$ in $S_a$ and $\varphi_0$ in $S_0$ is $I_a = I_{Q0} \sin (\varphi_a + \varphi_0)$, to which higher-order harmonics can also contribute. In a $S_aS_0S_b$ bijunction (with phase $\varphi_b$ in $S_b$), there exists in addition a quartet and a pair cotunneling supercurrent. The DC quartet supercurrent can be viewed as a non-local second-order harmonic

$$I_Q = I_{Q0} \sin (\varphi_a + \varphi_0 - 2\varphi_b),$$

while the pair cotunneling corresponds to a DC Josephson effect between $S_a$ and $S_b$ through $S_0$:

$$I_{PC} = I_{PC0} \sin (\varphi_a - \varphi_b).$$

More generally, assuming large enough transparencies, multipair currents $I_{a/b}$ in electrodes $S_a/S_b$ are obtained when differentiating the Josephson free energy with respect to the superconducting phases (assuming $\varphi_0 = 0$)

$$I_{a/b} = \sum_{n,m} I_{a/b(n,m)} \sin (n\varphi_a + m\varphi_b).$$

When voltages $V_{a/b}$ are applied to $S_{a/b}$, $\varphi_a$ and $\varphi_b$ acquire a time dependence, and in the special case where

$$nV_a + mV_b = 0,$$

the adiabatic approximation yields

$$d (n\varphi_a(t) + m\varphi_b(t))/dt = 0.$$  

The corresponding current component

$$I_{a/b(n,m)} \sin (n\varphi_a(t) + m\varphi_b(t))$$

and its higher harmonics are constant in time despite the applied voltages, thus leading to a DC current signaling the existence of a multipair resonance. An example of such a resonance is provided in Fig. 1 from a diagrammatic point of view, showing the case $2V_a + V_b = 0$ to lowest order. The voltage constraint allows to close a resonance path provided by one Andreev reflection in $S_b$ and $S_0$, two in $S_a$ as well as two CAR amplitudes in $S_0$. Note that in general these multipair resonances must coexist with the usual AC components

$$I_{a,(1,0)} = I_{0a} \sin \varphi_a(t), \quad I_{b,(0,1)} = I_{0b} \sin \varphi_b(t),$$

and with the MAR DC currents discussed in Ref. [16]. While this low-bias argument suggests the possibility of multipair resonances also at higher voltages, an exact out-of-equilibrium calculation at arbitrary voltage is still lacking, and it is discussed below.

III. HAMILTONIAN FORMALISM

The model Hamiltonian of the $S_aD_aS_0D_bS_b$ bijunction is written as

$$\hat{H} = \sum_j \hat{H}_j + \hat{H}_D + \hat{H}_T$$

where $\hat{H}_j$ is the Hamiltonian for the lead $S_j$ ($j = 0, a, b$), expressed with the Nambu spinors

$$\hat{H}_j = \sum_k \Psi_j^\dagger (\xi_k \sigma_z + \Delta \sigma_x) \Psi_j,$$

with the Pauli matrices acting in the Nambu space. $\hat{H}_D$ is the Hamiltonian of the two dots, with a single non-interacting level in each dot:

$$\hat{H}_D = \sum_{s,a}\epsilon_a d_{a,s}^\dagger d_{a,s}.$$
\( \hat{H}_T \) is for the tunneling between the dots and the electrodes:

\[
\hat{H}_T(t) = \sum_{j,k} \psi_{jk}^\dagger t_{ja} e^{i \varphi_j / 2} d_a + \text{h.c.},
\]

where \( d_a = (d_{a1} d_{a2}) \) is the Nambu spinor for dot \( a \), and \( t_{ja} \) is the tunneling amplitude between lead \( j \) and dot \( a \).

The phases are specified by the applied voltages \( \varphi_j(t) = \varphi_j^{(0)} + 2eV_j t / h \). The “bare” phases \( \varphi_j^{(0)} \), which are usually unimportant in an out-of-equilibrium setup, are relevant here in the transport calculations. The superconducting gaps \( \Delta \) are assumed identical and the couplings are taken symmetric. The width of the superconducting region \( S_0 \) is assumed to be negligible, a situation which corresponds to the maximum coupling between the two junctions forming the bijunction.

As the leads degrees of freedom are quadratic, they can be integrated out by averaging the evolution operator over these leads. We use for this a Keldysh path integral technique. The Green’s function \( \hat{G} \) of the dots which is non-perturbative in \( \hat{H}_T \), is obtained from a Dyson equation\(^6\) involving the free dots Green function, and electrode self-energies with both local and non-local propagators.\(^{23,24}\) The details for a multi-terminal structure with two quantum dots have been given in Ref. [24]. Due to the presence of the two dots, the Green function of the dots is a 2x2 matrix in the dot space:

\[
\hat{G}_{\alpha\beta}^{\eta\eta'}(t,t') = -i \left\langle T_C \left\{ d_{j\alpha}^\dagger(t) d_{j\beta}^{\eta'}(t') \right\} \right\rangle,
\]

where \( \eta, \eta' \) are Keldysh indices. The self-energy is also a 2x2 matrix in the dot space:

\[
\Sigma = \begin{pmatrix} \Sigma_{aa} & \Sigma_{ab} \\ \Sigma_{ba} & \Sigma_{bb} \end{pmatrix},
\]

and the component \( \Sigma_{\alpha\beta} \) (with \( \alpha, \beta = a, b \)) is given by a sum over the leads \( j \):

\[
\Sigma_{\alpha\beta}(t_1, t_2) = \sum_j \Gamma_{j,\alpha\beta} \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} -i\omega(t_1-t_2)e^{-i\sigma_z(V_{jt1}+\varphi_j^{(0)}/2)[\omega \cdot 1 - \Delta_j \cdot \sigma_z]} e^{+i\sigma_z(V_{jt2}+\varphi_j^{(0)}/2)}
\]

\[
\otimes \left[ \frac{-\Theta(\Delta_j - |\omega|)}{\Delta_j^2 - \omega^2} \tau_z + i \text{sign}(\omega) \frac{\Theta(|\omega| - \Delta_j)}{\sqrt{\Delta_j^2 - \omega^2}} \right] \left[ \frac{2f_\omega - 1}{2f_\omega} \right],
\]

where \( \Gamma_{j,\alpha\beta} = \pi n(0) t_{ja} t_{jb} \) and \( f_\omega \) is the Fermi function.

The average current from electrode \( j \) can then be computed using a Meir-Wingreen type formula\(^{22}\) generalized to superconductors\(^{23,24}\):

\[
\left\langle J_{ja} \right\rangle(t) = \frac{1}{2} \text{Tr} \left\{ \tau_z \otimes \sigma_z \int_{-\infty}^{+\infty} dt' \left( \hat{G}(t,t') \Sigma_j(t',t) - \Sigma_j(t',t') \hat{G}(t,t') \right) \right\},
\]

where \( \tau_z \) acts in Keldysh space, and \( \sigma_z \) in Nambu space, and the trace is taken in the Nambu-Keldysh space. For arbitrary voltages \( V_a \) and \( V_b \), the time-dependence of the system is described in terms of two independent Josephson frequencies \( \omega_a = 2eV_a / h \) and \( \omega_b = 2eV_b / h \), the Green function \( \hat{G}(t,t') \) is a function of two times, and solving the Dyson equation is a daunting task. However, when the voltages \( V_a \) and \( V_b \) applied to superconductors \( a \) and \( b \) are commensurate \((nV_a + mV_b = 0, \text { with } n \text { and } m \text { integers})\), the time-dependence of the system is periodic, with a period \( T = |m|2\pi / \omega_a = |n|2\pi / \omega_b \), where \( \omega_{a,b} = 2e|V_{a,b}| / h \) are the Josephson frequencies. As in the study of standard multiple Andreev reflection (MAR) between two superconductors\(^{23}\), it is then convenient to introduce the double Fourier transforms with summation over discrete domains in frequency:

\[
\hat{G}(t,t') = \sum_{n,m} \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} e^{-i\omega_n t + i\omega_m t'} \hat{G}_{nm}(\omega),
\]

\[
\Sigma(t,t') = \sum_{n,m} \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} e^{-i\omega_n t + i\omega_m t'} \Sigma_{nm}(\omega),
\]

where \( \omega_n = \omega + n\tilde{V} \), the frequency integration is performed over a finite domain \( F = [-\tilde{V}/2, \tilde{V}/2] \), and \( \tilde{V} \) is the smallest common multiple of \( |V_a| \) and \( |V_b| \). The advantage of this representation is that the Dyson equation for the full Green function \( \hat{G}_{nm}(\omega) \) is now a matrix equation:

\[
\hat{G}_{nm}(\omega) = \left[ \hat{G}_{0,nm}(\omega) - \Sigma_{nm}(\omega) \right]^{-1},
\]

where \( \hat{G}_{0,nm} \) is the dots Green function without coupling to the superconducting leads. This equation can be solved by limiting the discrete Fourier transforms to a cutoff energy \( E_c \), which gives finite matrices in Eq.(18). The cut-off energy \( E_c \) must be chosen large compared to all the relevant energies in the system. \( E_c \) defines a finite number of frequency domains \( n_{max} \). As the width
of each domain is \( \sim V \), one has \( n_{\text{max}} \sim \Delta/V \), which implies that obtaining numerically the full Green function becomes very expensive at very low voltage. Typical values which we have used in our calculations are in the range \( E_c \sim 5 \) to \( 10\Delta \).

From Eq.(14), we find that the self-energy in the double Fourier representation is (writing explicitly the 2x2 matrix of Nambu space)

\[
\hat{\Sigma}_{\alpha\beta,nm}(\omega_n) = \sum_j \Gamma_j \begin{pmatrix} \delta_{n,m} \bar{X}_j(\omega_n - \sigma_j V/2) & \delta_{n-m,\sigma_j} \bar{Y}_j(\omega_n + \sigma_j V/2) e^{-i\varphi_{j}^{(0)}} \\ \delta_{n+m,\sigma_j} \bar{X}_j(\omega_n - \sigma_j V/2) e^{i\varphi_{j}^{(0)}} & \delta_{n,m} \bar{Y}_j(\omega_n + \sigma_j V/2) \end{pmatrix},
\]

where \( \bar{X} \) and \( \bar{Y} \) are matrices in the Keldysh space:

\[
\bar{X}_j(\omega) = \begin{pmatrix} -\sqrt{\omega^2 - \Delta^2} & \Theta(\omega - \Delta) \frac{\pi}{2} \\ \Theta(\Delta - \omega) \frac{\pi}{2} & \sqrt{\omega^2 - \Delta^2} \end{pmatrix}, \quad \bar{Y}_j(\omega) = -\Delta \bar{Y}_j(\omega)/\omega.
\]

The expression of the Fourier transform of the current from dot \( \alpha \) to lead \( j \) is:

\[
\langle I_{j\alpha}(\omega') \rangle = \sum_{n,l} 2\pi \delta(\omega' - (n-l)V) \frac{1}{2} \int \frac{d\omega}{2\pi} \begin{pmatrix} \sigma_z \bar{\tau}_z \sum_{m} \{ \hat{G}_{nm}(\omega) \hat{\Sigma}_{j,m\ell}(\omega) - \hat{\Sigma}_{j,m\ell}(\omega) \hat{G}_{m\ell}(\omega) \} \end{pmatrix}_{\alpha\alpha},
\]

The DC current, which we study in the following sections, is obtained by taking \( \omega' = 0 \) in the last equation.

**IV. METALLIC JUNCTION REGIME**

We first consider the regime in which each dot mimics a metallic junction, achieved by energy levels out of resonance \( \epsilon_a > \Delta \) and choosing large couplings \( \Gamma_\alpha > \Gamma (\alpha = a, b, \text{and} \Gamma_\alpha = \sum_j \pi \nu(0)|t_{ja}|^2 \), where \( t_{ja} \) are tunneling couplings defined in Eq. (11), and \( \nu(0) \) the normal density of states of the electrodes at the Fermi energy \( \). We compute the DC currents \( I_{a/b} \) for different ratio of the voltages, satisfying \( V_a + V_b = 0 \). The results for the largest resonances \( (|n| + |m| \leq 3 \) in \( V_a + V_b = 0 \) are shown in the left panel of Fig. 2. One clearly sees that the resonances are easily distinguished from the phase-independent background current. The resonant multipair DC-current \( I_{M}^{MP} \) is a function of the combination \( n\varphi_a^{(0)} + m\varphi_b^{(0)} \), which implies a simultaneous crossing of \( n \) pairs from \( S_0 \) to \( S_a \) and \( m \) pairs from \( S_0 \) to \( S_b \). The upper right panel in Fig. 2 shows an example the phase dependence for \( n = 2 \) and \( m = 1 \), which is indeed a sinusoidal function of the combination \( 2\varphi_a^{(0)} + \varphi_b^{(0)} \). The existence of DC phase-coherent resonances despite large nonzero voltages is the result of new coherent modes connecting the three superconductors.

One of the lowest-order (and larger) resonances corresponds to quartets \( (V_a = -V_b) \), i.e. to the correlated transmission of two pairs from \( S_0 \) to \( S_a \) and \( S_b \), respectively. The “dual” lowest-order resonance corresponds to \( V_b = V_a \), where pairs cross from \( S_a \) to \( S_b \) by cotunneling through \( S_0 \). The sign of the multipair resonances is non-trivial. In particular, the quartet resonance is negative, which means that the current \( I_{a}(\varphi_a^{(0)} + \varphi_b^{(0)}) \) is of \( \pi \)-type, as shown in the lower right panel of Fig.2. Similar sign changes of the multipair current-phase relation are also obtained for certain high-order resonances. The \( \pi \)-shift is understood from a simple argument. It is related to the internal structure of a Cooper pair via the antisymmetry of its wavefunction, similarly to the \( \pi \)-junction behavior of a magnetic junction formed by a quantum dot with a localized spin\( ^{25} \). Starting from two Cooper pairs in \( S_0 \), the production of a non-local quartet consists in forming two non-locally entangled singletons in the dots \( D_a \) and \( D_b \). These two split pairs correspond to two CAR amplitudes, as those apparent in Figure 1. A non-local singlet is obtained by the operator \( \frac{1}{2}(d_{a\uparrow}^\dagger d_{b\downarrow}^\dagger - d_{a\downarrow}^\dagger d_{b\uparrow}^\dagger) \) acting on the empty dots. Applying this operator twice to describe a non-local quartet state leads to \( \Psi_{Q,D_a,D_b} = \frac{1}{\sqrt{4}}(\uparrow\downarrow)^2_a | \downarrow\uparrow \rangle_b \), which recast as the opposite of the product of a pair in \( D_a \) and another one in \( D_b \). A similar reasoning can be applied in order to explain the anomalous sign of higher-order harmonics.

**V. RESONANT DOTS REGIME**

We now investigate the possibility for optimizing the multipair resonances by tuning the dot levels, with \( \epsilon_a = -\epsilon_b = -0.4\Delta \) inside the gap, choosing small values of the couplings \( \Gamma_a = \Gamma_b = 0.1\Delta \). We focus on the quartet resonance \( V_a = -V_b \) for specificity (similar behavior is observed for the other resonances).

When the bias is small enough \( (V_b \lesssim 0.1\Delta) \) here), the system is in the adiabatic regime, and the current does
FIG. 2: (color online) “Broad” dots regime (metallic junctions): $|\varepsilon_{a,b}| = 6\Delta$, $\Gamma_{a,b} = 4\Delta$. Left: Amplitudes of the phase-dependent DC current $\langle I_a(\phi_a^{(0)}) \rangle$ for the main resonances (with $|n| + |m| \leq 3$), in units of $e\Delta/h$, centered around the values of the phase-independent current (small horizontal bars). Horizontal axis is $V_a/V_b$, with $V_b/\Delta = 0.3$. Upper right: Current $\langle I_a \rangle$, for the resonance $2V_a + V_b = 0$, as a function of the phases $\phi_a^{(0)}$ and $\phi_b^{(0)}$, showing the dependence in $2\phi_a^{(0)} + \phi_b^{(0)}$. Lower right: the current-phase relation $\langle I_a(\phi_b^{(0)}) \rangle$ at $\phi_a^{(0)} = 0$ for the resonance $V_a + V_b = 0$, which shows the $\pi$-phase behavior.

not change when $V_b$ is varied. We independently checked with a Matsubara formalism calculation (not shown) that this current is the same as the one obtained here at equilibrium ($V_b = 0$). The current-phase relations $\langle I_a(\phi_a^{(0)}) \rangle$ and $\langle I_b(\phi_b^{(0)}) \rangle$ for $V = 0.09\Delta$ are shown in the first panel of Fig. 3. These average currents are identical, thus are made only from a quartet component. They show a purely harmonic function of the phase $\phi_a^{(0)}$, and suggest a $\pi$-junction behavior for the quartet resonance near equilibrium.

When $V_b$ increases and the non-adiabatic regime is reached, drastic changes appear in the current-phase relations, as shown in the next panels of Fig. 3. There, both the sign and the (non-sinusoidal) shape of the current-phase relation changes rapidly with $V_b$ as it approaches the dot energy $|\varepsilon_b|$. The amplitude of the quartet current near the resonance is $\sim 1000$ times larger than the one in the adiabatic regime. This resonant effect of the dot levels is most apparent by plotting the critical current $I_c^Q$ (the maximum of the absolute value of the phase-dependent part of $I_a(\phi_a^{(0)})$) as a function of $V_b$. This is shown in the left panel of Fig. 4. $I_c^Q$ sharply increases and reaches a maximum around $V_b \simeq \varepsilon_b$. The large increase in the quartet current is due to a double resonant effect: first, as the dots have opposite energies $\varepsilon_a = -\varepsilon_b$, the formation of a quartet in the double dot as a pair in $D_a$ and a pair in $D_b$ is resonant (this is true for any voltage $V_b$); second when $V_b \simeq \varepsilon_b$, the tunneling of a pair from $D_a$ to $S_a$, and from $D_b$ to $S_b$, is also resonant.

Increasing $V_b$ further, e.g. $V_b \gtrsim 2\Delta/3$ in the present case, we see from the lower panels of Fig. 3 that the currents $\langle I_a(\phi_a^{(0)}) \rangle$ and $\langle I_b(\phi_b^{(0)}) \rangle$ start to deviate substantially. This implies the existence of another phase-
sensitive process different from the one responsible for multipair resonances. We call this current contribution $P^{\text{phMAR}}$ (for phase-sensitive MAR), as it is the result of the combination of a multipair process with MAR. The lowest order diagram contributing to $P^{\text{phMAR}}$ is shown in the right panel of Fig. 4. It can be seen as the interference of the amplitudes of two MAR processes at the $S_2S_0$ and $S_0S_1$ interfaces, each promoting a quasiparticle from an energy $\sim -\Delta$ in superconductor $S_0$ to an energy $\sim +\Delta$ in superconductor $S_0$. This diagram has a threshold at $V = 2\Delta/3$, corresponding to the observed value at which $P^{\text{phMAR}}$ becomes noticeable. However, unlike the usual MAR processes found in single junctions, this process (and similar ones of higher order) has the striking property of being phase-dependent.

Addressing more general resonances, the total DC current can be decomposed into 3 components, as inspired by Josephson's work\(^2\). Defining $I = (I_a, I_b, \phi = (\varphi_a, \varphi_b), V = (V_a, V_b), \epsilon = (\epsilon_a, \epsilon_b)$ one has $I(\phi, V, \epsilon) = I^{\text{MP}}(\phi, V, \epsilon) + P^{\text{phMAR}}(\phi, V, \epsilon) + I^{\text{QP}}(V, \epsilon)$. Assuming electron-hole symmetry to hold, for instance with flat normal metal density of states in the leads, one can show that in the situation studied here, the DC-current obeys the relation:

$$I(\phi(0), V, \epsilon) = -I(-\phi(0), -V, \epsilon). \quad (22)$$

Then the following properties hold: (i) The pure quasi-particle current $I^{\text{QP}}$ is phase-insensitive and odd in voltages. (ii) The coherent multipair current $I^{\text{MP}}$ is a function of $n\varphi(0) + m\varphi_b(0)$, it is odd in phases and even in voltages, just like the non-dissipative Josephson term. It satisfies $n(I_a) = n(I_b)$. (iii) The component $P^{\text{phMAR}}$ is even in phases and odd in voltages, like the dissipative ("cos $\phi$") Josephson component, but it becomes DC in a bijunction. This $P^{\text{phMAR}}$ component is also a function of $n\varphi(0) + m\varphi_b(0)$.

VI. CONCLUSIONS

We have shown by non-perturbative out-of-equilibrium calculations that coherent multipair and phase-dependent MAR processes appear in a superconducting bijunction. These are due to crossed Andreev reflection processes, through the formation of several entangled non-local pairs, and lead to signatures in the DC current with very specific phase and voltage dependence. A natural extension of the present work should focus on the role of local Coulomb interaction on the dots. In the metallic junction regime and in the resonant regime near the dot resonance, a self-consistent mean-field treatment could be applied (as done in Ref. [26] for a three terminal normal-superconducting setup with resonant dots). We expect that the same physical mechanisms would qualitatively produce the same effects. A more complex treatment would be required away from resonance, where interactions would have a larger impact and the Kondo mechanism could play an important role.

From an experimental standpoint, multipair resonances can be directly detected by transport measurements where one probes the nonlocal conductance $d(I_a)/dV_b$ as a function of $V_a, V_b$. The phase coherence of the multipair current, and its actual dependence in $\varphi_{ab}$, however, are more difficult to probe directly. One way would be to design specific SQUID geometries or microwave reflectivity experiments.\(^27\)
