Abstract. Fairly allocating distributed computing resources among workflow executions is critical to multi-user platforms. However, this problem remains mostly studied in clairvoyant and offline conditions, where task durations on resources are known, or the workload and available resources do not vary along time. We consider a non-clairvoyant, online fairness problem where the platform workload, task costs and resource characteristics are unknown and not stationary. We propose a fairness control loop which assigns task priorities based on the fraction of pending work in the workflows. Workflow characteristics and performance on the target resources are estimated progressively, as information becomes available during the execution. Our method is implemented and evaluated on 4 different applications executed in production conditions on the European Grid Infrastructure. Results show that our technique reduces slowdown variability by 3 to 7 compared to first-come-first-served.

1 Introduction

The problem of fairly allocating computing resources to application workflows rapidly arises on shared computing platforms such as grids or clouds. It must be addressed whenever the demand for resources is higher than the offer, that is, when some workflows are slowed down by concurrent executions. In some cases, unfairness makes the platform totally unusable, for instance when very short executions are launched concurrently with longer ones. We define fairness as in [123], i.e. as the variability in a set of workflows of the slowdown $\frac{M_{\text{multi}}}{M_{\text{own}}}$, where $M_{\text{multi}}$ is the makespan when concurrent executions are present, and $M_{\text{own}}$ is the makespan without concurrent executions.

We consider a software-as-a-service platform where users can, at any time, launch application workflows that will compete for computing resources. Our two main assumptions are (i) that the problem is online: new workflows can be submitted at any time, and resources may also join or leave at any time, and (ii) that the problem is non-clairvoyant: the execution time of a task on a given computing resource is unknown. Non-clairvoyance comes from the lack of application models in the platform and from the lack of information about the performance of computing and network resources. We also assume a limited control on the scheduler, i.e. that only task priorities can be changed to influence scheduling.
These conditions are representative of a large set of platforms, for instance the Virtual Imaging Platform (VIP) \cite{4} and other science gateways \cite{5,6,7} deployed on the European Grid Infrastructure (EGI)\cite{3}. These gateways offer applications deployed as workflows on shared computing platforms, but they have no information about when users will launch them and how long each task will last on a given resource.

Fairness among workflow executions has been addressed in several studies which, however, mostly assume clairvoyant conditions. For instance, the works in \cite{2,1,3,8,9,10} either directly minimize the slowdown (which assumes that makespans can be predicted) or use heuristics assuming that task durations and resources are known. A notable exception is found in \cite{11}, where a non-clairvoyant algorithm is proposed: nevertheless, it is purely offline, assuming that the tasks and resources are known and do not vary.

In this work, we propose an algorithm to control fairness on non-clairvoyant online platforms. Based on a progressive discovery of applications’ characteristics on the infrastructure, our method dynamically estimates the fraction of pending work for each workflow. Task priorities are then adjusted to harmonize this fraction among active workflows. This way, resources are allocated to application workflows relatively to their amount of work to compute. The method is implemented in VIP, and evaluated with different workflows, in production conditions, on the EGI. We use the slowdown as a post-mortem metric, to evaluate our method once execution times are known. Contributions of this paper are:

1. A new instantiation of our control loop \cite{12} to handle unfairness, consisting of (i) an online, non-clairvoyant fairness metric, and (ii) a task prioritization algorithm.
2. Experiments demonstrating that this method improves fairness compared to a first-come-first-served approach, in production conditions, and using 4 different applications.

The next section details our fairness control process, and section 3 presents experiments and results.

2 Fairness control process

Workflows are directed graphs of activities spawning sequential tasks for which the executable and input data are known, but the computational cost and produced data volume are not. Workflow graphs may include conditional and loop operators. Algorithm 1 summarizes our fairness control process. Fairness is controlled by allocating resources to workflows according to their fraction of pending work. It is done by re-prioritising tasks in workflows where the unfairness degree $\eta_u$ is greater than a threshold $\tau_u$. This section describes how $\eta_u$ and $\tau_u$ are computed, and details the re-prioritization algorithm.

**Measuring unfairness: $\eta_u$.** Let $m$ be the number of workflows with an active activity; a workflow activity is active if it has at least one waiting (queued) or
Algorithm 1 Main loop for fairness control

1: input: \( m \) workflow executions
2: while there is an active workflow do
3: wait for timeout or task status change in any workflow
4: determine unfairness degree \( \eta_u \)
5: if \( \eta_u > \tau_u \) then
6: re-prioritize tasks using Algorithm 2
7: end if
8: end while

running task. The unfairness degree \( \eta_u \) is the maximum difference between the fractions of pending work:

\[
\eta_u = W_{\text{max}} - W_{\text{min}},
\]

with \( W_{\text{min}} = \min\{W_i, i \in [1, m]\} \) and \( W_{\text{max}} = \max\{W_i, i \in [1, m]\} \). All \( W_i \) are in \([0, 1]\). For \( \eta_u = 0 \), we consider that resources are fairly distributed among all workflows; otherwise, some workflows consume more resources than they should. The fraction of pending work \( W_i \) of a workflow \( i \in [1, m] \) is defined from the fraction of pending work \( w_{i,j} \) of its \( n_i \) active activities:

\[
W_i = \max_{j \in [1, n_i]} (w_{i,j})
\]

All \( w_{i,j} \) are between 0 and 1. A high \( w_{i,j} \) value indicates that the activity has a lot of pending work compared to the others. We define \( w_{i,j} \) as:

\[
w_{i,j} = \frac{Q_{i,j}}{Q_{i,j} + R_{i,j}P_{i,j}} \cdot \hat{T}_{i,j},
\]

where \( Q_{i,j} \) is the number of waiting tasks in the activity, \( R_{i,j} \) is the number of running tasks in the activity, \( P_{i,j} \) is the performance of the activity, and \( \hat{T}_{i,j} \) is its relative observed duration. \( \hat{T}_{i,j} \) is defined as the ratio between the median duration \( \hat{t}_{i,j} \) of the completed tasks in activity \( j \) and the maximum median task duration among all active activities of all running workflows:

\[
\hat{T}_{i,j} = \frac{\hat{t}_{i,j}}{\max_{v \in [1,m], w \in [1,n^*_i]} (\hat{t}_{v,w})}
\]

Tasks of an activity all consist of the following successive phases: setup, inputs download, application execution and outputs upload; \( \hat{t}_{i,j} \) is computed as \( \hat{t}_{i,j} = \hat{t}_{\text{setup}} + \hat{t}_{\text{input}} + \hat{t}_{\text{exec}} + \hat{t}_{\text{output}} \). Medians are progressively estimated as tasks complete. At the beginning of the execution, \( \hat{T}_{i,j} \) is initialized to 1 and all medians are undefined; when two tasks of activity \( j \) complete, \( \hat{t}_{i,j} \) is updated and \( \hat{T}_{i,j} \) is computed with equation 4. In this equation, the max operator is computed only on \( n^*_i \leq n_i \) activities with at least 2 completed tasks, i.e. for which \( \hat{t}_{i,j} \) can be determined. We are aware that using the median may be inaccurate. However, without a model of the applications’ execution time, we must rely on observed task durations. Using the whole time distribution (or at least its few first moments) may be more accurate but it would complexify the method.
In Eq. 3, the performance $P_{i,j}$ of an activity varies between 0 and 1. A low $P_{i,j}$ indicates that resources allocated to the activity have bad performance for the activity; in this case, the contribution of running tasks is reduced and $w_{i,j}$ increases. Conversely, a high $P_{i,j}$ increases the contribution of running tasks, therefore decreases $w_{i,j}$. For an activity $j$ with $k_j$ active tasks, we define $P_{i,j}$ as:

$$P_{i,j} = 2 \left( 1 - \max_{u \in [1,k_j]} \left\{ \frac{t_u}{t_{i,j} + t_u^{\text{med}}} \right\} \right),$$

where $t_u = t_u^{\text{setup}} + t_u^{\text{input}} + t_u^{\text{exec}} + t_u^{\text{output}}$ is the sum of the estimated durations of task $u$’s phases. Estimated task phase durations are computed as the max between the current elapsed time in the task phase (0 if the task phase has not started) and the median duration of the task phase. $P_{i,j}$ is initialized to 1, and updated using Eq. 5 only when at least 2 tasks of activity $j$ are completed.

If all tasks perform as the median, i.e. $t_u = t_{i,j}$, then $\max_{u \in [1,k_j]} \left\{ \frac{t_u}{t_{i,j} + t_u^{\text{med}}} \right\} = 0.5$ and $P_{i,j} = 1$. Conversely, if a task in the activity is much longer than the median, i.e. $t_u \gg t_{i,j}$, then $\max_{u \in [1,k_j]} \left\{ \frac{t_u}{t_{i,j} + t_u^{\text{med}}} \right\} \approx 1$ and $P_{i,j} \approx 0$. This definition of $P_{i,j}$, considers that bad performance results in a few tasks blocking the activity. Indeed, we assume that the scheduler doesn’t deliberately favor any activity and that performance discrepancies are manifested by a few “unlucky” tasks slowed down by bad resources. Performance, in this case, has a relative definition: depending on the activity profile, it can correspond to CPU, RAM, network bandwidth, latency, or a combination of those. We admit that this definition of $P_{i,j}$ is a bit rough. However, under our non-clairvoyance assumption, estimating resource performance for the activity more accurately is hardly possible because (i) we have no model of the application, therefore task durations cannot be predicted from CPU, RAM or network characteristics, and (ii) network characteristics and even available RAM are shared among concurrent tasks running on the infrastructure, which makes them hardly measurable.

Thresholding unfairness: $\tau_u$. Task prioritisation is triggered when the unfairness degree is considered critical, i.e. $\eta_u > \tau_u$. Thresholding consists in clustering platform configurations in two groups: one for which unfairness is considered acceptable, and one for which task re-prioritization is needed. We determine $\tau_u$ from execution traces, for which different thresholding approaches can be used. For instance, we could consider that $x\%$ of the platform configurations are unfair while the rest are acceptable. The choice of $x$, however, would be arbitrary. Instead, we inspect the modes of the distribution of $\eta_u$ to determine a threshold with a practical justification: values of $\eta_u$ in the highest mode of the distribution, i.e. which are clearly separated from the others, will be considered unfair.

In this work, the distribution of $\eta_u$ is measured from traces collected in VIP between January 2011 and April 2012 [13]. The data set contains 680,988 tasks (including resubmissions and replications) of 2,941 workflow executions executed by 112 users; task average queueing time is about 36 min. Applications deployed in VIP are described as GWENDIA workflows [14] executed using the MOTEUR workflow engine [15]. Resource provisioning and task scheduling are provided by
DIRAC [16]. Resources are provisioned online with no advance reservations. Tasks are executed on the biomed virtual organization (VO) of the European Grid Infrastructure (EGI) which has access to some 150 computing sites worldwide and to 120 storage sites providing approximately 4 PB of storage. Fig. 1 (left) shows the distribution of sites per country supporting the biomed VO.

The unfairness degree $\eta_u$ was computed after each event found in the data set. Fig. 1 (right) shows the histogram of these values, where only $\eta_u \neq 0$ values are represented. This histogram is clearly bi-modal, which is a good property since it reduces the influence of $\tau_u$. From this histogram, we choose $\tau_u = 0.2$.

**Task prioritization.** The action taken to cope with unfairness is to increase the priority of $\Delta_{i,j}$ waiting tasks for all activities $j$ of workflow $i$ where $w_{i,j} - W_{\text{min}} > \tau_u$. Running tasks cannot be pre-empted. Task priority is an integer initialized to 1. $\Delta_{i,j}$ is determined so that $\tilde{w}_{i,j} = W_{\text{min}} + \tau_u$, where $\tilde{w}_{i,j}$ is the estimated value of $w_{i,j}$ after $\Delta_{i,j}$ tasks are prioritized. We approximate $\tilde{w}_{i,j}$ as:

$$\tilde{w}_{i,j} = \frac{Q_{i,j} - \Delta_{i,j}}{Q_{i,j} + R_{i,j}P_{i,j}} \hat{T}_{i,j},$$

which assumes that $\Delta_{i,j}$ tasks will move from status queued to running, and that the performance of new resources will be maximal. It gives:

$$\Delta_{i,j} = Q_{i,j} - \left\lfloor \frac{(\tau_u + W_{\text{min}})(Q_{i,j} + R_{i,j}P_{i,j})}{\hat{T}_{i,j}} \right\rfloor,$$

where $\lfloor \rfloor$ rounds a decimal down to the nearest integer value.

Algorithm 2 describes our task re-prioritization. $\text{maxPriority}$ is the maximal priority value in all workflows. The priority of $\Delta_{i,j}$ waiting tasks is set to $\text{maxPriority} + 1$ in all activities $j$ of workflows $i$ where $w_{i,j} - W_{\text{min}} > \tau_u$. Note that this algorithm takes into account scatter among $W_i$ although $\eta_u$ ignores it (see Eq. 1). Indeed, tasks are re-prioritized in *any* workflow $i$ for which $W_i - W_{\text{min}} > \tau_u$.

The method also accommodates online conditions. If a new workflow $i$ is submitted, then $R_{i,j} = 0$ for all its activities and $\hat{T}_{i,j}$ is initialized to 1. This leads to $W_{\text{max}} = W_i = 1$, which increases $\eta_u$. If $\eta_u$ goes beyond $\tau_u$, then $\Delta_{i,j}$ tasks of activity $j$ of workflow $i$ have their priorities increased to restore fairness. Similarly, if new resources arrive, then $R_{i,j}$ increase and $\eta_u$ is updated accordingly. Table 1 illustrates the method on a simple example.

### 3 Experiments and results

Experiments are performed on a production grid platform to ensure realistic conditions. Evaluating fairness in production by measuring the slowdown is not
Algorithm 2 Task re-prioritization

1: input: $W_1$ to $W_m$ //fractions of pending works
2: maxPriority = max task priority in all workflows
3: for i=1 to m do
4:   if $W_i - W_{\text{min}} > \tau_u$ then
5:     for j=1 to $a_i$ do
6:       // $a_i$ is the number of active activities in workflow $i$
7:       if $w_{i,j} - W_{\text{min}} > \tau_u$ then
8:         Compute $\Delta_{i,j}$ from equation 6
9:         for p=1 to $\Delta_{i,j}$ do
10:           if 3 waiting task q in activity j with priority $\leq$ maxPriority then
11:             q.priority = maxPriority + 1
12:         end if
13:       end if
14:     end for
15:   end if
16: end for
17: end for

straightforward because $M_{\text{own}}$ (see definition in the introduction) cannot be directly measured. As described in Section 3.1, we estimate the slowdown from task durations, but this estimation may be challenged. Thus, Experiment 1 evaluates our method on a set of identical workflows, where the variability of the measured makespan can be used as a fairness metric. In Experiment 2, we add a very short workflow to this set of identical workflow, which was one of the configurations motivating this study. Finally, Experiment 3 considers the more general case of 4 different workflows with heterogeneous durations.

3.1 Experiment conditions

Fairness control was implemented as a MOTEUR plugin receiving notifications about task and workflow status changes. Each workflow plugin forwards task status changes and $\tilde{t}_{i,j}$ values to a service centralizing information about all the active workflows. This service then re-prioritizes tasks according to Algorithms 1 and 2. As no online task modification is possible in DIRAC, we implemented task prioritization by canceling and resubmitting queued tasks to DIRAC with new priorities. This implementation decision adds an overhead to task executions. Therefore, the timeout value used in Algorithm 1 is set to 3 minutes.

The computing platform for these experiments is the biomed VO used to determine $\tau_u$ in Section 2. To ensure resource limitation without flooding the production system, experiments are performed only on 3 sites of different countries (France, Spain and Netherlands). Four real medical simulation workflows are considered: GATE [17], SimuBloch, FIELD-II [18], and PET-Sorteo [19]; their main characteristics are summarized on Table 2.

Three experiments are conducted. Experiment 1 tests whether unfairness among identical workflows is properly addressed. It consists of three GATE workflows sequentially submitted, as users usually do in the platform. Experiment 2 tests if the performance of very short workflow executions is improved by the fairness mechanism. Its workflow set has three GATE workflows launched sequentially, followed by a SimuBloch workflow. Experiment 3 tests whether unfairness among different workflows is detected and properly handled. Its workflow
Let’s consider two identical workflows composed of one activity with 6 tasks, and assume the following values at time $t$:

<table>
<thead>
<tr>
<th>$i$</th>
<th>$Q_{i,1}$</th>
<th>$R_{i,1}$</th>
<th>$P_{i,1}$</th>
<th>$T_{i,1}$</th>
<th>$W_{i,1}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>3</td>
<td>10</td>
<td>0.9</td>
<td>1.0</td>
</tr>
<tr>
<td>2</td>
<td>6</td>
<td>0</td>
<td>-</td>
<td>1.0</td>
<td>1.0</td>
</tr>
</tbody>
</table>

Values unknown at time $t$ are noted ‘-’. Workflow 1 has 2 completed and 3 running tasks with the following phase durations (in arbitrary time units):

<table>
<thead>
<tr>
<th>$u$</th>
<th>$t_{\text{setup}}$</th>
<th>$t_{\text{input}}$</th>
<th>$t_{\text{exec}}$</th>
<th>$t_{\text{output}}$</th>
<th>$t_u$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2</td>
<td>2</td>
<td>4</td>
<td>1</td>
<td>9</td>
</tr>
<tr>
<td>2</td>
<td>1</td>
<td>2</td>
<td>3</td>
<td>2</td>
<td>8</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
<td>3</td>
<td>5</td>
<td>-</td>
<td>7</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>2</td>
<td>-</td>
<td>-</td>
<td>5</td>
</tr>
<tr>
<td>5</td>
<td>1</td>
<td>-</td>
<td>-</td>
<td>-</td>
<td>1</td>
</tr>
</tbody>
</table>

We have $t_{\text{setup}}^{\text{setup}} = 2$, $t_{\text{input}}^{\text{input}} = 2$, $t_{\text{exec}}^{\text{exec}} = 4$, and $t_{\text{output}}^{\text{output}} = 2$. Therefore, $t_{\text{exec}}^{\text{exec}} = 10$.

The configuration is clearly unfair since workflow 2 has not started tasks. Eq. 1 gives $\eta = 0.73$. As $\eta > \tau = 0.2$, the platform is considered unfair and task re-prioritization is triggered.

$$\Delta_{2,1} = Q_{2,1} - \left[\tau_{2,1}(Q_{2,1} + R_{2,1} + P_{2,1})\right] = 6 - \left[0.2 + 0.27\right] = 4$$

At time $t' > t$:

<table>
<thead>
<tr>
<th>$i$</th>
<th>$Q_{i,1}$</th>
<th>$R_{i,1}$</th>
<th>$P_{i,1}$</th>
<th>$T_{i,1}$</th>
<th>$W_{i,1}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>3</td>
<td>10</td>
<td>0.8</td>
<td>1.0</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>4</td>
<td>-</td>
<td>1.0</td>
<td>1.0</td>
</tr>
</tbody>
</table>

Now, $\eta = 0.04 < \tau$. The platform is considered fair and no action is performed.

### Table 1. Example

<table>
<thead>

---

4 [https://dirac.france-grilles.fr](https://dirac.france-grilles.fr)
first-come, first-served policy imposed by submitting workflows with decreasing priority values.

Two different fairness metrics are used. The unfairness $\mu$ is the area under the curve $\eta_u$ during the execution:

$$\mu = \sum_{i=2}^{M} \eta_u(t_i) \cdot (t_i - t_{i-1}),$$

where $M$ is the number of time samples until the makespan. This metric measures if the fairness process can indeed minimize its own criterion $\eta_u$. In addition, the slowdown $s$ of a completed workflow execution is defined by:

$$s = \frac{M_{\text{multi}}}{M_{\text{own}}}$$

where $M_{\text{multi}}$ is the makespan observed on the shared platform, and $M_{\text{own}}$ is the estimated makespan if it was executed alone on the platform. In our conditions, $M_{\text{own}}$ is estimated as:

$$M_{\text{own}} = \max_{p \in \Omega} \sum_{u \in p} t_u,$$

where $\Omega$ is the set of task paths in the workflow, and $t_u$ is the measured duration of task $u$. This assumes that concurrent executions only impact task waiting time, not performance. For instance, network congestion or changes in performance distribution resulting from concurrent executions are ignored. We use $\sigma_s$, the standard deviation of the slowdown to quantify the unfairness. In Experiment 1, the standard deviation of the makespan ($\sigma_m$) is also used.

3.2 Results and discussion

Experiment 1 (identical workflows): Fig. 2 shows the makespan, unfairness degree $\eta_u$, makespan standard deviation $\sigma_m$, slowdown standard deviation $\sigma_s$ and unfairness $\mu$ for the 4 repetitions. The difference among makespans and unfairness degree values are significantly reduced in all repetitions of Fairness. Both Fairness and No-Fairness behave similarly until $\eta_u$ reaches the threshold value $\tau_u = 0.2$. Unfairness is then detected and the mechanism triggers task prioritization. Paradoxically, the first effect of task prioritization is a slight increase of $\eta_u$. Indeed, $P_{i,j}$ and $T_{i,j}$, that are initialized to 1, start changing earlier in Fairness than in No-Fairness due to the availability of task duration values to compute $\tilde{t}_{i,j}$. Note that $\eta_u$ reaches similar maximal values in both cases, but reaches them faster in Fairness. The fairness mechanism then manages to decrease $\eta_u$ back under 0.2 much faster than it happens in No-Fairness when tasks progressively complete. Finally, slight increases of $\eta_u$ are sporadically observed towards the end of the execution. This is due to task replications performed by MOTEUR: when new tasks are created, the fraction of pending work $W$ increases, which has an effect on $\eta_u$. Quantitatively, the fairness mechanism reduces $\sigma_m$ up to a factor of 15, $\sigma_s$ up to a factor of 7, and $\mu$ by about 2.

Experiment 2 (very short execution): Fig. 3 shows the makespan, unfairness degree $\eta_u$, unfairness $\mu$ and slowdown standard deviation. In all cases, the
makespan of the very short SimuBloch executions is significantly reduced for Fairness. The evolution of $\eta_u$ is coherent with Experiment 1: a common initialization phase followed by an anticipated growth and decrease for Fairness. Fairness reduces $\sigma_s$ up to a factor of 5.9 and unfairness up to a factor of 1.9.

Table 3 shows the execution makespan ($m$), average wait time ($\overline{w}$) and slowdown ($s$) values for the SimuBloch execution launched after the 3 GATE. As it is a non-clairvoyant scenario where no information about task execution time and future task submission is known, the fairness mechanism is not able to give higher priorities to SimuBloch tasks in advance. Despite that, the fairness mechanism speeds up SimuBloch executions up to a factor of 2.9, reduces task average wait time up to factor of 4.4 and reduces slowdown up to a factor of 5.9.

Experiment 3 (different workflows): Fig. 4 shows slowdown, unfairness degree $\eta_u$, unfairness $\mu$ and slowdown standard deviation $\sigma_s$ for the 4 repetitions. Fairness slows down GATE while it speeds up all other workflows. This is because GATE is the longest and the first to be submitted; in No-Fairness, it is favored by resource allocation to the detriment of other workflows. The evolution of $\eta_u$ is similar to Experiments 1 and 2. $\sigma_s$ is reduced up to a factor of 3.8 and unfairness up to a factor of 1.9.

In all 3 experiments, fairness optimization takes time to begin because the method needs to acquire information about the applications which are totally unknown when a workflow is launched. We could think of reducing the time of this information-collecting phase, e.g. by designing initialization strategies maximizing information discovery, but it couldn’t be totally removed. Currently, the method works best for applications with a lot of short tasks because the first few tasks can be used for initialization, and optimization can be exploited for the
### 4 Conclusion

We presented a method to address unfairness among workflow executions in an online and non-clairvoyant environment. We defined a novel metric $\eta_u$ quantifying unfairness based on the fraction of pending work in a workflow. It compares workflow activities based on their ratio of queuing tasks, their relative durations, and the performance of resources where tasks are running. Performance is defined from the variability of task duration in the activity; good performance is assumed to lead to homogeneous task durations. To separate fair configurations from unfair ones, a threshold on $\eta_u$ was determined from platform traces. Unfair configurations are handled by increasing the priority of pending tasks in the least remaining tasks. The worst-case scenario is a configuration where the number of available resources stays constant and equal to the number of tasks in the first submitted workflow: in this case, no action could be taken until the first workflow completes, and the method would not do better than first-come-first-served. Pre-emption of running tasks should be considered to address that.

Fig. 3. Experiment 2 (very short execution). Top: comparison of the makespans; middle: unfairness degree $\eta_u$; bottom: unfairness $\mu$ and slowdown standard deviation.
performing workflows. This is done by estimating the number of running tasks that these workflows should have to bring $\eta_u$ under the threshold value.

The method was implemented in the MOTEUR workflow engine and deployed on EGEE with the DIRAC resource manager. We tested it on four applications extracted from VIP, a science gateway for medical simulation used in production. Three experiments were conducted, to evaluate the capability of the method to improve fairness (i) on identical workflows, (ii) on workflow sets containing a very short execution and (iii) on different workflows. In all cases, results showed that our method can very significantly reduce the standard deviation of the slowdown, and the average value of our metric $\eta_u$.

The work presented here is a step in our attempt to control computing platforms where very little is known about applications and resources, and where situations change over time. Our works in [12,20] consider similar platform conditions but they target completely different problems, namely fault-tolerance and granularity control. We believe that results of this paper are the first ones presented to control fairness in such conditions which are often met in production platforms. Future work could include task pre-emption in the method, and a sensitivity analysis on the influence of the relative task duration ($T_{i,j}$) and of the performance factor ($P_{i,j}$).
