Abstract: In this paper, we are interested in the finite-time average consensus problem for multi-agent systems or wireless sensor networks. This issue is formulated in a discrete-time framework by utilizing a linear iteration scheme, where each node repeatedly updates its value as a weighted linear combination of its own value and those of its neighbors. Unlike most of research in literature, this work deals with the foremost step, called configuration step, during which the consensus protocol is to be set up in each agent. Designing consensus protocols can be viewed as a matrix factorization problem. For connected undirected graphs, we propose a learning method for solving such matrix factorization problem in a distributed way. More precisely, we first show how solving this problem for the particular case of strongly regular graphs. Then, a distributed gradient back-propagation algorithm is derived for the general case. The performance of the proposed algorithm is evaluated by means of simulation results.

Keywords: Protocol design, finite-time average consensus, back-propagation algorithm, matrix factorization, self-configuration.

1. INTRODUCTION

The consensus issue in networks of autonomous agents has been widely investigated in various fields, including computer science and engineering. In such networks, according to an a priori specified rule, each agent updates its state based on the information received from its neighbors with the aim of reaching an agreement to a common value. When the common value corresponds to the average of the initial states, average consensus is to be achieved. Average consensus algorithms are commonly used as building block for distributed control, estimation or inference algorithms. In the recent literature, one can find average consensus algorithms embedded in the Distributed Kalman filter, Olfati-Saber (2007); Distributed Least Squares algorithm, Bolognani et al. (2008); Distributed Alternating Least Squares for tensors factorization, Kibangou and de Almeida (2010); Distributed Principal Component Analysis, Valcarel Macua et al. (2010); or distributed joint input and state estimation, Esna-Ashari et al. (2012), to cite few.

In order to run an average consensus algorithm, two main steps are required: the configuration step (also called design step) and the execution step. During the configuration step, the consensus protocol is to be uploaded in each agent. Such a task can be achieved through a self-configuration algorithm instead of resorting to a network manager. Self-configuration can include graph discovering and distributed decision on some parameters. For instance, if the protocol is the maximum-degree weights one, each agent first computes the number of its neighbors before running a max-consensus algorithm for computing the maximum degree of the underlying graph. In the case of the Metropolis-Hasting based protocol, also called local-degree weights, each agent compares its degree with that of its neighbors in order to compute the weights of the average consensus protocol. One commonly used protocol is the constant edge weights, or graph Laplacian based average consensus protocol, where a common step-size is used by all the agents. Asymptotic convergence is then guaranteed if the step-size is strictly positive and lower than $2/\lambda_1(L)$ where $\lambda_1(L)$ stands for the largest graph Laplacian eigenvalue. Even though there are some simple bounds that give choices for the step-size without requiring exact knowledge of the Laplacian spectrum, agents have to agree in an adequate step-size. To the best to our knowledge, there is no paper dealing with self-configuration protocols for the constant edge weights based average consensus protocol. It is worth noting that the step-size influences on the speed of convergence of the average consensus algorithm when using constant edge weights. That’s why some recent works have been devoted to accelerating the speed of convergence of consensus algorithms by solving some optimization problems in a centralized way; the goal being to reduce the spectral gap between the matrix of weights and the average consensus matrix $J_N = \frac{1}{N}11^T$, where $N$ stands for the number of agents of the network, Xiao and Boyd (2004); Kokiopoulou and Frossard (2009).

Since average consensus can be embedded in more sophisticated distributed algorithms, protocols that guarantee a minimal execution time are more appealing than those ensuring asymptotic convergence. For this purpose, several contributions dedicated to finite-time consensus have been recently published in the literature. In most of them, in particular those formulated in a continuous-time framework, the goal is to agree on a common value in finite-time without necessarily specifying such a common value, Cortes (2006); Wang and Xiao (2010); Shaofu Yang and Lu (2012). Finite-time average consensus protocols have been mainly proposed in a discrete-time framework. In Sundaram and Hadjicostis (2007), a finite-time consensus algorithm based on the minimal polynomial of the weight matrix was proposed. However, the design of this protocol requires a strong knowledge on the underlying
network topology. Therefore, a decentralized calculation of the minimal polynomial was proposed. An improvement of this method has been proposed in Yuan et al. (2013). The author has proposed algorithms to compute the consensus value using the minimal number of observations of an arbitrary chosen node in a network. However, the computation of the rank of a given matrix and that of its kernel are needed. Therefore, the computational cost is the weakness of these methods. In Ko (2010) and Georgopoulos (2011), the finite-time average consensus was formulated as a matrix factorization problem. The resulting solution yields a link scheduling on the complete graph to achieve finite time consensus. Such a scheduling is to be controlled by a central node. Following the idea of matrix factorization, Laplacian based joint diagonalizable matrices were suggested in Kibangou (2011, 2012). The proposed solutions make use of the graph Laplacian spectrum. However, the implementation of these protocols during the configuration step was not really discussed. In fact, for self-configuration of Laplacian based finite-time average consensus protocols, distributed estimation of Laplacian eigenvalues is required. Such a task can be carried out by means of distributed or decentralized algorithms such as those proposed in Tran and Kibangou (2013), Sahai et al. (2012), and Franceschelli et al. (2009).

The purpose of this paper is to study a new algorithm for self-configuration protocols for finite-time average consensus where weighted matrices are not necessarily based on the graph Laplacian. The aim is to design protocols that allow achieving average consensus in the fastest possible time, possibly as fast as the diameter of the underlying graph. More precisely, we solve a matrix factorization problem in a distributed way.

The remainder of this paper is organized as follows: in Section 2, we give the preliminary views of the theory and formulate the problem under study. The particular case of strongly regular graphs is studied in Section 3. Then, a gradient back-propagation algorithms is derived in Section 4 for solving a matrix factorization problem in a distributed way. The performance of the proposed algorithm is evaluated in Section 5 by means of simulation results before concluding the paper.

2. PROBLEM STATEMENT

Through out this paper, we consider a connected undirected graph \( G(V,E) \), where \( V = \{v_1, v_2, \ldots, v_N\} \) is the set of vertices of graph \( G \), and \( E \subset V \times V \) is the set of edges. Vertices \( v_i \) are agents in a network connected according to \( E \). Before formulating the problem, we first state some basic notations:

- \( N = \{v_i \in V : (v_i, v_j) \in E\} \) stands for the set of neighbors of node \( v_i \).
- Given two vertices \( v_i \) and \( v_j \), the distance \( dist(v_i, v_j) \) is the length of the shortest path between \( v_i \) and \( v_j \).
- The eccentricity \( ecc(v_i) \) of a vertex \( v_i \) is the greatest distance between \( v_i \) and any other vertex \( v_j \in V \).
- The radius \( r(G) \) of a graph is the minimum eccentricity of any vertex.
- The diameter \( d(G) \) of a graph is the maximum eccentricity of any vertex in the graph, i.e. \( d(G) = \max_{v_i,v_j} \text{dist}(v_i, v_j) \).
- We denote by \( A \) the adjacency matrix of the graph. Its entries \( A_{i,j} \) being equal to one if \( (v_i, v_j) \in E \) and zero elsewhere.

- The graph Laplacian \( L \) is defined as the matrix with entries

\[
  l_{ij} \text{ given by: } l_{ij} = \begin{cases} 
  \sum_{k=1; k \neq i}^{N} A_{ik}, & \text{if } j = i \\
  -A_{ij}, & \text{if } j \neq i
  \end{cases}
\]

- A regular graph is a graph where each vertex has the same number of neighbors; i.e. every vertex has the same degree or valency. A regular graph with vertices of degree \( k \) is called a \( k \)--regular graph.

Now, let us state the finite-time average consensus problem.

For each agent \( v_i \in V \), let \( x_i(t) \) be its state at time-step \( t \). At each time-step each node updates its state as

\[
x_i(t) = w_i^{t} x_i(t-1) + \sum_{j \in N_i} w_{ij} x_j(t-1).
\]

(1)

Defining the state of the network as:

\[
x(t) = [x_1(t), x_2(t), \ldots, x_N(t)]^T,
\]

where \( N \) is the number of nodes in the network, the dynamics of the network is given as follows:

\[
x(t) = W U x(t-1), \quad t = 1, 2, \ldots,
\]

(2)

where \( W \), with entries \( w_{ij} \), is consistent with the graph topologies, i.e. \( W \in \mathcal{G} \) where \( \mathcal{G} \) is the set of matrices that can be factorized as \( W = Q \circ (I_k + A) \) where \( Q \) stands for an arbitrary square matrix, \( I_k \) being the \( N \times N \) identity matrix, whereas \( \circ \) denotes the Hadamard matrix product that corresponds to an entry-wise matrix product.

Given any set of initial values \( x(0) \), we are interested in a finite sequence of weighted matrices, \( W_t \in \mathcal{G} \), that allows all agents to reach average consensus in a finite number of steps (or finite-time) \( D \), i.e. \( x(D) = \frac{1}{N} \mathbf{1}^T x(0) = J_N x(0) \). Ultimately, we desire a finite sequence of matrices \( \{W_1, W_2, \ldots, W_D\} \) such that

\[
x(D) = \prod_{t=1}^{D} W_t x(0) = J_N x(0) \quad \text{for all } x(0) \in \mathbb{R}^N,
\]

(3)

meaning that

\[
\prod_{t=1}^{D} W_t = J_N.
\]

(4)

Within this framework the fundamental problems concern existence, minimality, and design issues: For a given graph \( G \), does there exist a finite sequence of matrices \( W_t \in \mathcal{G} \) such that (4) is achieved? If it exists, what is the minimal value of \( D \)? How can we carry out such a factorization?

The existence issue has been deeply considered in Ko (2010) and Georgopoulos (2011). It has been pointed out that no solution exists if the factor matrices \( W_t \) are all equal except if the graph is complete. For trees and graphs with minimum diameter spanning tree, solutions have been also provided. For more general graphs, solutions based on graph Laplacian have been recently introduced in closed-form, Kibangou (2011) and Kibangou (2012). The factors matrices are constrained to be equal to \( W_t = \alpha_t I + \beta_t L \) where \( \alpha_t \) and \( \beta_t \) are parameters to be designed. More precisely, in Kibangou (2012), the solution was given by \( \alpha_t = 1 \) and \( \beta_t = -\frac{1}{\lambda_{k}(L)} \) \( \lambda_k(L) \) being a nonzero Laplacian eigenvalue. Therefore, the number of factor matrices is equal to the number of distinct nonzero Laplacian eigenvalues. Intuitively, since the diameter of the graph characterizes the time necessary for a given information to reach all the agents in the network, the number of factor matrices cannot be lower than the diameter \( d(G) \). According to the results in Kibangou (2012), the number \( D \) is upper bounded by \( N - 1 \). For distance regular graphs, Brouwer et al. (1989), \( D = d(G) \). In Hendrickx
et al. (2012), an upper bound is given by $2r(G)$ where $r(G)$ stands for the radius of the graph.

Now, for a given value of $D$ lower bounded by the diameter of the graph and upper bounded by two times the radius of the graph, how could we compute the factor matrices without the Laplacian constraint? Strictly speaking, equation (4) gives rise to a system of multivariate polynomial equations, which can be solved using Groebner basis theory and Buchberger's algorithm, in Buchberger (1976). However, the computational complexity and centralized nature of such an approach is crippling.

In what follows, we first consider the particular case of strongly regular graphs where closed form solutions of the factorization problem can be obtained in a distributed way, Godsil and Royle (2001). Then, for the general case, we design a distributed method that makes use of learning sequences. Indeed, in most systems where communications are involved, learning sequences are used for communication channel identification or for synchronization. These sequences are used during the mandatory configuration step before transmitting informative data, i.e. running average consensus in our case. We assume that all the agents know the average of the learning sequence.

3. CLOSED FORM SOLUTION OF THE MATRIX FACTORIZATION PROBLEM FOR STRONGLY REGULAR GRAPHS

A graph $G$ is said to be strongly regular, SRG($N,k,a,c$), if it is neither complete nor empty and there are integers $k$, $a$, and $c$ such that:

- $G$ is regular with valency $k$;
- any two adjacent vertices have exactly $a$ common neighbors;
- any two distinct non-adjacent vertices have exactly $c$ common neighbors.

These parameters are linked as follows:

$$(N - k - 1)c = k(k - a - 1).$$

In addition, the following interesting property can be stated as in Godsil and Royle (2001):

$$A^2 - (a - c)A - (k - c)I_N = NcJ_N.$$  

Examples of strongly regular graphs are: Petersen graph (SRG($10,3,0,1$)), Clebsch graph (SRG($16,5,0,2$)), Payley graphs (SRG($q^2, q, q - 2, q - 1$)), with $q$ congruent 1 (mod 4), two dimensional Hamming graphs (SRG($n^2, 2n - 2, n - 2, 2$, $n > 2$), a cycle with $N < 6$. The most obvious property of the strongly regular graphs is that the diameter is equal to two ($d(G) = 2$).

Let us state the following theorem:

**Theorem 1.** Let $\gamma$ be a nonzero free parameter. For a strongly regular graph SRG($N,k,a,c$), average consensus can be reached in two steps with the weights given by the matrices $W_i = w_iI_N + \gamma A$, $i = 1,2$ with $\gamma_1 = \frac{1}{\sqrt{5}}$, $\gamma_2 = \frac{1}{\sqrt{5}}(1 - \frac{c}{2})$, and $w_2 = \frac{\gamma}{2} \left( c - a \pm \sqrt{(a - c)^2 + 4(k - c)} \right)$.

**Proof:** With matrices $W_i = w_iI_N + \gamma A$, $i = 1,2$, we get:

$$W_2W_1 = (w_2w_1 + (k - c)\gamma A)I_N + ((w_2 + w_1)\gamma + \gamma_2)A.$$  

As a consequence, the matrices $W_1$ and $W_2$ are factors of $J_N$ if and only if $w_2w_1 + (k - c)\gamma = 0$, $(w_2 + w_1)\gamma + \gamma_2 = 0$, and $Nc\gamma = 1$. After few manipulations, we get the following equation to solve: $Nc\gamma w_2^2 + (a - c)w_2 - \gamma_2(k - c) = 0$, whose discriminant $\Delta = (a - c)^2 + 4(k - c)$ is strictly positive. Meaning that for any nonzero value of the free parameter $\gamma$, we can always get a factorization of $J_N$ with parameters in the form $W_i = w_iI_N + \gamma A$.

Assuming that the structural property is known, the agents can determine the factor matrices in a distributed way. Indeed, the number $\alpha$ of common parameters can be easily computed by comparing the ID of neighbors then, using (5), parameter $c$ can be deduced as $c = \frac{k(k - a - 1)}{N - k - 1}$. Agreement on $\gamma_2$, after a random selection, can be reached using a max or a min consensus. For example: Considering a Petersen Graph (SRG($10,3,0,1$)). Using (6), we get the equation: $\frac{1}{10}A^2 + \gamma A - \frac{1}{10}I_N = J_N$. With an arbitrary $\gamma_2$, by Theorem 1, we can compute:

$$w_2 = \frac{\gamma}{2} \left( 1 \pm \frac{1}{5} \right); \gamma_1 = -\frac{1}{10}.$$  

Then, these results give us $W_1, W_2$ as follows:

For $w_2 = 2\gamma_2$:

$$W_1 = -\frac{1}{10}\gamma_2I_N + \frac{1}{10}A; W_2 = 2\gamma_2I_N + \gamma_2A.$$  

For $w_2 = -\gamma_2$:

$$W_1 = \frac{1}{5}\gamma_2I_N + \frac{1}{10}A; W_2 = -\gamma_2I_N + \gamma_2A.$$  

In both cases, we can easily check that:

$$W_2W_1 = -\frac{1}{10}I_N + \frac{1}{10}A + \frac{1}{10}A^2 = J_N.$$  

Deriving closed form solutions is not always possible. Therefore, in next section, we derive a distributed solution of the matrix factorization problem for more general graphs.

4. DISTRIBUTED SOLUTION OF THE MATRIX FACTORIZATION PROBLEM

Let $\{x_i,p(0),y_i,p\}$, $i = 1, \ldots, N$, $p = 1, \ldots, P$, be the input-output signals defining the learning sequences, with $y_i,p = y_p = \frac{1}{N} \sum x_i,p(0)$. Our aim is to estimate the factor matrices $W_i$, $i = 1, \ldots, D$, by minimizing the quadratic error

$$E(W_1, \ldots, W_D) = \frac{1}{2} \sum_{i = 1}^{N} \sum_{p = 1}^{P} (x_i,p(D) - y_p)^2,$$  

with $x_i,p(t) = \sum_{j \in N_i \cap \{i\}} w_{ij}^p x_{j,p}(t-1)$, $w_{ij}^p$ being the entries of matrices $W_i$. We can rewrite the cost function (8) as

$$E(W_1, \ldots, W_D) = \frac{1}{2} \sum_{i = 1}^{N} \sum_{p = 1}^{P} (x_i,p(D) - Y)^2,$$  

where $\|\cdot\|_F$ stands for the Frobenius norm, $Y = J_NX(0)$, $X$ and $Y$ being $N \times P$ matrices with $y_i,p$ and $x_i,p$ as entries, respectively. We assume that $X(0)X(0)^T = I_N$ which means

Max and Min consensus can be reached in a finite number of steps, Olfati-Saber and Murray (2004)
that the input vector is orthogonal. For instance, vectors of the
canonical basis of $\mathbb{R}^N$ can be used as inputs. Hence, we
can note that $E(W_1, \ldots, W_D) = \frac{1}{2} \left\| \prod_{i=1}^D W_i - \mathbf{J} \right\|_F^2$, meaning
that minimizing (9) is equivalent to solving the factorization
problem (4):

$$\{W_i^*\}_{i=1, \ldots, D} = \arg \min_{(W_1), \ldots, (W_D)} \frac{1}{2} \sum_{p=1}^P \text{tr} \left( E_p(W) E_p^T(W) \right),$$

(10)

with

$$E_p(W) = \prod_{i=1}^D W_i x_p(0) - y_p,$$

(11)

where $\text{tr}(\cdot)$ denotes the trace operator and $y_p = J x_p(0)$.

Denoting $E_p(W) = \frac{1}{2} \text{tr} \left( E_p(W) E_p^T(W) \right)$, the solution of this
optimization problem can then be obtained iteratively by means
of a gradient descent method:

$$W_i := W_i - \alpha \frac{\partial E_p(W)}{\partial W_i},$$

(12)
or a stochastic gradient one:

$$W_i := W_i - \alpha \frac{\partial E_p(W)}{\partial W_i},$$

(13)

where the gradient of the cost function is approximated by the
gradient at a single input-output sequence. In what follows, we
resort to a stochastic gradient method. For this purpose, we first
state the following technical lemma:

**Lemma 1.** The derivatives of the cost function $E_p(W) = \frac{1}{2} \text{tr} \left( E_p(W) E_p^T(W) \right)$ with $E_p(W)$ defined in (11) can be computed as follows:

$$\frac{\partial E_p(W)}{\partial W_i} = \delta_{i,p} x_p^T(t-1) + \delta_{i,p} x_p^T(D-1) \quad \text{for } i = 1, \ldots, D,$$

(14)

where $\delta_{D,p} = x_p(D) - \bar{x}_p$ is the difference between the actual
output and the desired output with $x_p = y_p = \frac{1}{N} \sum_{i=1}^N x_i(0)$; and

$$\delta_{i-1,p} = W_i^T \delta_{i,p}, \quad t = 1, \ldots, D.$$  

**Proof.** See Appendix. ■

Applying the results of Lemma 1, the updating scheme of the
optimization algorithm is as follows:

$$W_i[m+1] = W_i[m] - \alpha \frac{\partial E_p(m)(W)}{\partial W_i}$$

(15)

where $p(m) \in \{1, \ldots, P\}$, and $m$ stands for the $m$th iteration
of the optimization process.

The gradient descent algorithm (15) acts by alternating the following
steps: the learning sequence is first propagated forward.
Then the error between the targeted output and $x(D)$ is computed and then propagated. This mechanism is similar to the
gradient backpropagation algorithm. Its convergence has been
well studied in the literature, see Chong and Zak (2012) and
Mangasarian and Solodov (1994) for instance. Convergence
towards a local minimum is guaranteed if the step-size $\alpha$ is ap-
propriately chosen ($0 < \alpha < 1$). Such a step-size also influences
on speed of convergence of the algorithm. Several rules have
been proposed for accelerating the convergence speed. How-
however, these techniques are not consistent with the distributed
framework of the proposed algorithm. One trick to speed-up
the convergence is to add a regularization term in the cost function
to be minimized.

$$\{W_i^*\}_{i=1, \ldots, D} = \arg \min_{(W_1), \ldots, (W_D)} \sum_{p=1}^P E_p(m)(W)$$

$$+ \frac{1}{2} \sum_{i=1}^D \beta \| W_i[m] - W_i[m-1] \|^2.$$

(16)

By minimizing such a cost function, the update equation is given by:

$$W_i[m + 1] = W_i[m] - \alpha \delta_{i,p} x_p^T(t-1) + \beta (W_i[m] - W_i[m-1]).$$

Entry-wise, each agent updates its entries as follows:

$$w_{ij}^t := w_{ij}^{t-1} - \alpha \delta_{i,j} x_j(t-1) + \beta (w_{ij}^t - w_{ij}^{t-1}),$$

where $\delta_{i,j}$ is the $i$th entry of $\delta_i$ and $x_j(t-1)$ the $j$-th entry
of $x(t-1)$. $\alpha$ and $\beta$ are learning rate and momentum rate
respectively.

The distributed algorithm is then described as follows:

1. **Initialization:**
   - Number of steps $D$, number of patterns $P$
   - Learning sequence $(x_i(0), y_p)$, where $i = 1, \ldots, N$
   - $p = 1, \ldots, P$, with $y_p = \frac{1}{N} \sum_{i=1}^N x_i(0)$.
   - Random initial weighted matrices $W_i[0], t = 1, \ldots, D,$
   - $W_i[-1] = 0$.
   - Learning rate: $0 < \alpha < 1$.
   - Momentum terms: $0 < \beta < 1$.
   - Select a threshold $\gamma$
   - Set $m = 0$

2. **Set $p = 0;**
   - (a) Set $p := p + 1$.
   - (b) Select the corresponding input-output sequence
     $x_i(0) = x_i(0), \hat{x} = y_p$.
   - (c) Learning sequence propagation:
     $$x_i(t) = \sum_{j \in \mathcal{N}(i)} w_{ij}^t [m] x_j(t-1), \quad t = 1, \ldots, D.$$
   - (d) Error computation:
     $$\delta_{i,D} = x_i(D) - \hat{x}; \quad e_{i,p} = \delta_{i,D}^T.$$
   - (e) Error propagation:
     $$\delta_{i,t-1} = \sum_{j \in \mathcal{N}(i)} w_{ij}^t [m] \delta_{j,t}, \quad t = D, \ldots, 2.$$
   - (f) Matrices updating: for $t = 1, \ldots, D, i = 1, \ldots, N$, and
     $j \in \mathcal{N}(i) \cup \{i\}$,
     $$w_{ij}^t[m + 1] = w_{ij}^t[m] - \alpha \delta_{i,j} x_j(t-1)$$
     $$+ \beta (w_{ij}^t[m] - w_{ij}^{t-1}[m-1]).$$
   - (g) Increment $m$.
   - (h) If $p = P$, compute the mean square error
     $$E_i = \frac{1}{P} \sum_{p=1}^P e_{i,p},$$
     else return to 2a.
(i) If \( E_t < \gamma \) stop the learning process else return to 2.

5. SIMULATION RESULTS

In this section, we consider two examples of different network topologies to evaluate the developed algorithm. The learning sequence is constituted with the vectors of the canonical basis of \( \mathbb{R}^N \).

The performance of designed protocols is evaluated by means of the MSE:

\[
MSE = \frac{1}{NP} \sum_{i=1}^{N} \sum_{p=1}^{P} (x_{t,p}(D) - y_p)^2.
\]

5.1 Example 1:

Fig. 1. 6-node graph

Let us consider the graph depicted in Figure 1. Its diameter is \( d(G) = 3 \) while the radius is \( r(G) = 2 \). The eigenvalues of the corresponding Laplacian matrix \( L \) are: 0, 1, 2, 3 and 5. According to Kibangou (2012), the factorization of the average consensus matrix by means of graph Laplacian based consensus matrices needs \( D \) factor matrices, \( D \) being the number of nonzero distinct eigenvalues of the Laplacian matrix, this number being, in general, greater or equal to the diameter of the graph. Therefore, we get the following factorization:

\[
(I_N - L)(I_N - \frac{1}{2}L)(I_N - \frac{1}{3}L)(I_N - \frac{1}{5}L) = J_6,
\]

meaning that consensus is achieved in 4 steps. Since the optimal number of steps is not a priori known, we run the algorithm for different values of \( D \) taken in the interval of \( [d(G), 2r(G)] \). Here, the two possible values of \( D \) are 3 and 4.

Fig. 2. MSE comparison for the two possible numbers of factors

Figures 2 shows that the best solution is obtained for \( D = 3 \). With the proposed algorithm for design protocol we get a number of step lower than that given by Laplacian based matrices proposed in Kibangou (2011, 2012). The weighted matrices are:

\[
W_1 = \begin{pmatrix}
-0.4028 & 0.0415 & 0 & 0 & 0 & 0 \\
0.4418 & -0.0455 & 0 & 0 & 0 & 0 \\
0.5749 & 0 & 0.0537 & 0.0537 & 0.9219 & 0 \\
0 & 0.4053 & 0.3675 & 0.3675 & 0 & 0.3902 \\

\end{pmatrix}
\]

We can easily check that:

\[
W_3 W_2 W_1 = J_6.
\]

Now, let us consider the finite-time consensus protocol in its execution step, i.e. after the configuration step. For arbitrary initial values, the trajectories of the state of the network are depicted in Figure 3(a). Exact average consensus is achieved in 3 steps. When using the optimal constant edge weights protocol \( W = I_N - \alpha L \) where \( \alpha = \frac{1}{\lambda_{\max}(L)^2} \) proposed in Xiao and Boyd (2004), we get the trajectories in Figure 3(b). Showing that more iterations are actually needed to reach consensus.

(b) Trajectory of an asymptotic consensus protocol by using optimal constant edge weights protocol

5.2 Example 2:

Now considering the network in Figure 4, we can see that diameter of this graph equals to 2, and the radius of the graph equals to 2. Running the proposed algorithm, the performance in Figure 5 tells us that this network cannot achieve the average consensus in 2 steps, which is diameter of a graph. Such a result has been demonstrated analytically by Hendrickx et al. (2012). However, by running the algorithm as well as varying the value of \( D \) in the interval of \( [d(G), 2r(G)] \), we can pick the optimal \( D \) in this case. The final MSE was obtained by considering a sufficient large number of iterations.

For this topology, \( D = 3 \) gives us the best solution for finite-time average consensus, see in Figure 5. Also, the trajectory of

6. CONCLUSION

In this paper, we have proposed a way for distributively designing the finite-time average consensus protocol. By using a learning sequence, we have shown how to solve a matrix factorization problem (4) in a fully distributed way. The method is based on the gradient back-propagation method. The factorization gives rise to factor matrices that are not necessarily symmetric or stochastic. Given the diameter and the radius of the graph, we can find out the optimal value of the number of steps necessary for reaching average consensus. However, the speed of convergence of the proposed algorithm is still an actual issue. For this purpose, future works encompass optimal step-size for gradient descent based method and other optimization methods with a particular focus to large size graphs. In addition, the dependency of the convergence speed on the learning sequence is to be studied. Hence, another interesting issue will be the design of optimal learning sequences. Beside that, the robustness of the finite-time average consensus should be definitely paid a great attention.

APPENDIX

The consensus network being a linear system we know that $x_p(t) = W_t x_p(t-1)$, therefore we can explicitly write the output according to the weighting matrix of interest, i.e. $x_p(D) = W_0 x_p(D - 1) = \prod_{j=1}^{D} W_j x_p(t-1)$, $t = 1, \ldots, D - 1$. Equivalently, by defining $Z_{t+1} = \prod_{j=1}^{t+1} W_j$, we get $x_p(D) = Z_{t+1} W_t x_p(t-1)$. The cost function can be written as

$$E_p(W) = \frac{1}{2}r((W_{DD} x_p(D-1) - x_p)(W_{DD} x_p(D-1) - x_p)^T)$$

We can easily deduce that $\frac{\partial E_p(W)}{\partial W_{ij}} = \delta_{D,p} x_p^T (D-1)$ with $\delta_{D,p} = x_p(D) - x_p$.

Now, we can express the cost function according to any matrix $W_t, t = 1, \ldots, D - 1$ as

$$E_p(W) = \frac{1}{2} [r((Z_{t+1} W_t x_p(t-1) - x_p)(Z_{t+1} W_t x_p(t-1) - x_p)^T)]$$

Expanding the above expression and taking into account the linearity of the trace operator yield

$$E_p(W) = \frac{1}{2} [r((Z_{t+1} W_t x_p(t-1) x_p^T (t-1) W_t^T Z_{t+1}) + r(Z_{t+1} W_t x_p(t-1) x_p^T (t-1) W_t^T Z_{t+1}) - r(x_p x_p(t-1) W_t^T Z_{t+1}))$$

Now, computing the derivative, we get:

$$\frac{\partial E_p(W)}{\partial W_t} = \frac{1}{2} [2d Z_{t+1} W_t x_p(t-1)x_p(t-1)^T - 2d Z_{t+1} x_p x_p(t-1)^T]$$
