(Received 15 February 2002; accepted 16 June 2003)

Abstract – The sensitivity to frost in the living inner bark of trees have been hypothesised to be influenced by acid rain and N deposition through changes in nutrient balance and carbon metabolism. At the Skogaby experimental site, situated in southern Sweden, Norway spruce in control plots, plots fertilized with ammonium sulphate and plots fertilized with mineral nutrients except N were compared in this respect. Frost sensitivity was measured by electrolytic leakage and expressed as an index of injury. The results showed increased sensitivity to frost in the bark of trees treated with continuous applications of ammonium sulphate for 11 years. This was probably not only a direct effect of high nitrogen availability, but also caused by insufficient levels of other nutrients due to the rapid growth and changes in soil chemistry induced by the addition of ammonium sulphate. Mainly Mg and K seemed to be of importance for retaining a good frost resistance, supporting the hypothesis that nutrient imbalances increases the risk for development of frost related bark lesions in southern Sweden.

Résumé – Effets d’un excès d’azote sur la sensibilité au froid de l’écorce interne de l’Épicéa. On a émis l’hypothèse selon laquelle la sensibilité au froid de la partie vivante interne de l’écorce des arbres serait influencée par les pluies acides et les dégâts azotés, par suite de changements de l’équilibre d’azote et du métabolisme du carbone. À la station expérimentale de Skogaby, située en Suède méridionale, on a comparé le comportement, sous cet angle, de l’épicéa dans un dispositif comportant des parcelles fertilisées avec divers nutrients à l’exclusion d’azote, ainsi que des parcelles témoins. La sensibilité au froid a été évaluée par des mesures de conductivité électrolitique, et exprimée par un indice de l’importance des dommages observés. Les résultats montrent une sensibilité accrue au froid de l’écorce des arbres traités d’une manière continue pendant 11 ans avec du sulfate d’ammoniac. Cela est probablement dû, non seulement à l’effet direct d’une importante disponibilité en azote, mais aussi à un niveau insuffisant de celle des autres nutrients, cela résultant d’une croissance plus rapide ainsi que de modifications des équilibres chimiques du sol induits par l’apport du sulfate d’ammoniac. Le rôle de Mg et K semble particulièrement important pour assurer une bonne résistance au froid, ce qui appuie l’hypothèse selon laquelle des déséquilibres entre nutrients augmentent le risque de lésions de l’écorce dans le sud de la Suède.

1. INTRODUCTION

Frost damage results from temperatures decreasing lower than hardening status. They are usually caused by a rapid drop in temperature to below 0 °C, following a warm period in the spring or autumn, or following a mild period at any time during the winter when the trees are not fully hardened. Spring frosts are therefor especially harmful when the trees have started to deharden [37, 40, 41]. It has been hypothesised that during the 1980’s and 1990’s the unusually mild winters in southern Sweden caused Norway spruce trees to deharden early, before the risk of frost damage had passed. The resulting damage was observed as bark necrosis and resin flow [4, 5]. Furthermore, until they had healed, these lesions remained susceptible to invasion by pathogenic insects and fungi, further increasing the damage and even killing the tree in severe cases [37].

High N deposition levels and acid rain can influence the trees’ sensitivity to frost, as well as their sensitivity to other stress factors such as drought and pathogen attacks, via effects on the nutrient status [27]. Leaching of nutrients from needles and increased soil acidification which causes leaching of nutrients from the soil may contribute to nutrient imbalance in trees [13, 28]. Increased growth, in response to increases in N availability, may induce deficiencies in other nutrients as a result of dilution effects [1]. These signs of nutrient imbalance have been observed in southern Sweden. Between 1985 and 1994, the K and Cu concentrations in Norway spruce needles decreased from more than sufficient to below optimum levels.

Changes in nutrient status can influence frost hardness by affecting carbon production, respiration and allocation, as well as via changes in membrane properties and osmotic potential [8]. Excess N in the tree may cause a shortage of carbohydrates, due to changes in carbon partitioning towards protein synthesis and arginine formation [2, 12]. The maintenance respiration rates of needles are positively correlated to the concentration of N [36]. Hence enhanced N concentrations may increase respiration rates and thereby reduce non-structural carbohydrate reserves, including the sugars that are used for protection against frost during the winter [32]. Excess N may also cause buds to break earlier and delay the onset of dormancy, increasing the risk of damage caused by frost episodes in spring and autumn [9, 10]. Adverse effects can also occur if the N concentration is unbalanced in relation to other nutrients, for instance B, causing a relative nutrient deficiency [2].

Conifers with nutrient deficiencies are generally considered to have an increased sensitivity to frost, and fertilization with the deficient elements will increase the cold tolerance. However, contradictory results have been obtained, and this can be explained by differences among species, tissues and phenological states [8, 17, 22, 33]. Decreased sensitivity to frost has been observed in Sitka spruce needles with low concentrations of N, P or K [18] and Scots pine needles with a low concentration of K [19]. This may be due to a reduced growth rate causing increased concentrations of soluble carbohydrates and amino acids that act as cryoprotectants [26].

The aim of this study was to test the influence of needle and bark nutrient status in Norway spruce on the frost sensitivity; for this purpose we used the Skogaby field experimental site in southern Sweden. Here the nutrient status of trees has been altered artificially either by increasing N and S deposition or by adding a vitality fertilizer, i.e. N-free fertilizer. We hypothesised that:

- (a) trees fertilized with ammonium sulphate have an increased sensitivity to frost in the bark;
- (b) the sensitivity to frost is related to nutrient deficiency and to an imbalance between N and other nutrients in the needles;
- (c) the frost sensitivity is related to the concentrations of sugar and starch in the bark;
- (d) the concentrations of sugar and starch in the bark are related to the nutrient status;
- (e) effects of nutrient imbalance are more pronounced in large trees treated with ammonium sulphate, due to a higher ability to take up N.

2. MATERIALS AND METHODS

2.1. Field site

The experimental area is situated in south-western Sweden (lat. 56° 33′, long. 13° 13′) about 16 km from the coast and 95–115 m above sea level.

+5 °C as a control. Three bark samples were frozen during 30 min in a freezing cabinet, ProfiMaster National Lab, holding the test temperature. The bark samples were acclimatized at +5 °C for 10 h before freezing, and thawed at +5 °C for 10 h in order to avoid extreme temperature gradients, i.e. room temperature, which would have exacerbated the damage. When thawed, 5 mL of 3% propanol was added to all the bark samples. They were then incubated in darkness for 24 h at 25 °C. During that time ions from the bark tissue leaked into the propanol solution, the greater the injury, the more leaked ions. Conductivity was measured with a CDM92 conductivity meter (Radiometer, Copenhagen) with a reference temperature of 20 °C. All samples were autoclaved for 20 min at 120 °C and reincubated in darkness for 24 h at 25 °C. After which the conductivity was measured. An index of injury ranging from 0 = no freezing damage to 100 = completely killed was assumed to be from soil dust deposition [7, 43]. The optimum levels for mean ratios of mineral nutrients to nitrogen (%) in the current year needles were set according to Lindén [25].

2.5. Sugar and starch analysis

Two pieces of bark from each tree were freeze-dried and ground into fine powder in a ball mill. The powder was put into percolators. The sugars were extracted with 80% ethanol and the starch was extracted with 35% perchloric acid from 25 mg of the bark samples according to Hansen and Möller [16].

2.6. Statistics

The dataset was analyzed using ANOVA. Treatment and size-class were treated as fixed effects and block as a random effect. Interactions between treatment and size-class were analysed. The Tukey Kramer post hoc test was used for evaluating treatment effects. The ANOVA assumptions were tested for all variables, and no transformation was required. Regression analyses and stepwise multiple regression with forward selection of variables were used for studying the relations between frost sensitivity, concentrations of mineral nutrients and carbohydrates. All statistical analysis was done according to Sokal and Rohlf [38] using Systat 5.2.1 for Macintosh. Standard deviation was indicated by ±.

3. RESULTS

In the plots treated with ammonium sulphate (Tabs. II and III) the foliar N concentration was significantly higher, while concentrations of Ca, Mg, Zn and B were lower than in the control and vitality fertilized plots. The needle concentrations of P and Zn, and the bark concentrations of P and K (Tab. III and Fig. 3) were significantly greater in the vitality fertilized plots. The K/N, P/N and Mg/N ratios were below the level considered necessary according to Hansen and Möller [16].

Rohlf [38] using Systat 5.2.1 for Macintosh. Standard deviation was indicated by ±.
for optimal growth in the trees treated with ammonium sulphate, whereas the Cu/N ratio was below optimum in all plots (Fig. 1).

The bark was more damaged at –20 °C (on average 16.8% ± 10.9) than at –10 °C (on average 5.3% ± 5.9) (p < 0.0001). The index of injury at –10 °C did not differ among treatments. The trees treated with ammonium sulphate were more sensitive at –20 °C than trees from control and vitality fertilized plots (p = 0.02) (Fig. 2).

There was a significant positive correlation between the frost sensitivity at –20 °C and the concentration of N in needles (p = 0.02, r² = 0.38). Stepwise multiple regression analysis did not include N, but the concentration of K in bark and needles, B and Ca in needles and Mn in bark (p = 0.002, r² = 0.67). Thus, the highest correlation was found with a combination of mineral nutrients in bark and needles. Trees with a Mg/N ratio below the level for optimal growth were significantly more frost sensitive at –20 °C (p = 0.01).

The concentrations of sugar (on average 144 mg·g⁻¹ ± 24) and starch (on average 55 mg·g⁻¹ ± 14 mg·g⁻¹) did not differ among treatments and were not correlated to the indices of injury. According to multiple regression analysis, the concentration of sugar was related to the concentrations of K and P in needles (p = 0.03, r² = 0.31), and the concentration of starch was related to the concentrations of K in needles, Zn and Na in the bark (p = 0.008, r² = 0.48).

There were no significant differences in frost sensitivity between small and large trees for any treatment or temperature, but large trees treated with ammonium sulphate tended to be the most frost sensitive (Fig. 2). Large trees had higher concentrations of K (p = 0.03) and sugar (p = 0.04) in the bark than small trees (Fig. 3).

4. DISCUSSION

The effects of the different fertilizer regimes on tree nutrient status were consistent with earlier findings from the Skogaby site [30, 35]. The nutrient imbalance in trees treated with ammonium sulphate developed gradually over the years since the start of the treatment, and can be explained by a dilution effect caused by increased growth, increased soil acidification and decreased base saturation in the soil [31]. During the first three years of the treatment, trees fertilised with ammonium sulphate grew approximately 25% more than those in the control plots [29]. However, after a few years of relatively high growth, the growth rate decreased to equal that of the control trees in 1996, and from 1997 onward fell below that of the control trees [34], showing the nutrient impact on tree metabolism. Increased concentrations of P, K, Ca, Mg and B in the needles have been measured in the trees treated with the vitality fertilizer.
In this study, only increased concentrations of P and Zn were detected.

The frost damage caused at $-10$ °C was too slight, only a few percent, to detect either differences among treatments or any influence of nutrient status. By contrast, the effects at $-20$ °C clearly indicated the negative influence of the addition of ammonium sulphate. The correlation between frost sensitivity and N concentration in the needles suggested an effect of imbalance between N and other nutrients, and this was detected as a higher frost sensitivity in trees with a lower than optimal Mg/N ratio. The concentrations of K in bark was selected by the stepwise multiple regression analysis as the variable with the highest explanatory value. This may, however, not imply a causal relationship as experiments on conifer seedlings have found that K does not affect the level of hardiness [11, 24]. The concentration of K has a large impact on the transpiration [23], and this may affect the frost sensitivity indirectly.

The concentrations of sugar and starch were related to the concentration of K in needles in combination with other nutrients. Although the trees treated with ammonium sulphate had a concentration of N above 15 mg/g, indicating an accumulation of arginin [6], there was no relation between N and carbohydrates. Nor was there any correlation between the concentration of carbohydrates and the frost sensitivity. The concentrations of different sugars may be more relevant than the total sum, as frost resistance in Norway spruce seedlings has been found to be strongly correlated with the accumulation of sucrose and raffinose [3].

In general, larger trees have a larger leaf area and thus transpire more than small trees. This causes a relatively larger uptake of ions with high diffusion coefficients in the soil, such as NO$_3^-$ and K$^+$, which follow the mass flow of water [15]. This could be the reason for higher concentrations of K in large trees, and may have contributed to the higher concentration of sugar. However, the large trees were hypothesised to encounter a nutrient imbalance earlier than small trees. This was not evident in this study, although there was a tendency for the large trees treated with ammonium sulphate to be the most frost sensitive.

It was difficult to assess the impact of a specific nutrient in this field experiment since the treatments have affected several nutrients at the same time. Also, a correlation to nutrient concentrations and ratios can only be expected if there is a difference between the trees studied [20]. For instance, the Cu/N ratio was below the level considered optimal in all treatments, hence all trees were affected approximately equally and a potential influence on frost sensitivity and carbohydrate concentrations is then less likely to be detected. In another study on 30–40 year-old Norway spruce in southern Sweden, the frost sensitivity of the bark and hardiness status of needles were related to the concentrations of P and Mg in bark and needles, which in turn was related to differences in soil fertility between the study sites. The results also indicated influence of K [20]. Both this and the present study support the hypothesis that nutrient imbalances increases the risk for development of frost related bark lesions in southern Sweden.

5. CONCLUSIONS

- Continuous applications of ammonium sulphate for 11 years increased the frost sensitivity of Norway spruce bark.

- Although difficult to assess the impact of a specific nutrient, mainly Mg and K seemed to be of importance for retaining a good frost resistance. Low levels of these nutrients were probably caused by accelerated growth rates and growth dilution. Soil acidification and ion leakage associated with the ammonium sulphate fertilization further decreased their availability.

- The frost sensitivity was not related to the concentrations of sugar and starch in the bark, although the concentrations of sugar and starch in the bark were related to the tree nutrient status.

- Nutrient imbalance was not aggravated in large trees growing in plots treated with ammonium sulphate.

Acknowledgements: We are grateful to Anders Jonshagen for sampling the needles, to Ragnhild Ohlin, Siv Billberg, Irené Persson, Maj-Lis Gernersson and Tommy Ohlson for help with the analysis, to Dr. Lucy Sheppard and two anonymous reviewers for valuable comments on the manuscript, and to Abigail Sykes for revising the language. We would like to thank the Skogaby project for allowing us to take the samples. This study was financially supported by SUFOR, the Swedish Mistra foundation.
