SUMMARY

HOECHST reagent, a DNA-specific fluorochrome, was used on serial sections of plant material which had been fixed, paraffin embedded, then deparaffinized. This procedure, which allows conservation of the material and observation of 7 μm thick serial sections, could be used for the detection of low number of M.L.O.s and the study of their development in the plant.

In resin-embedded material, polychromatic staining of 0.5-1 μm thick sections, in particular with thionin-acridine orange, allowed much more accurate M.L.O. detection than the monochromatic staining commonly used.

Additional key words : *Light microscopy, fluorochrome, paraffin, resin, semi-thin section, thionin, acridine orange, methylene blue, azure A, safranin.*

RÉSUMÉ

Etude comparative de méthodes utilisant le réactif de Hoechst et les colorations polychromatiques pour la détection des mycoplasmes chez les végétaux.

Le réactif de HOECHST, fluorochrome spécifique de l'ADN, a été utilisé sur coupes sériées de matériel végétal fixé, inclus dans la paraffine, puis déparaffiné. Ce procédé qui permet la conservation du matériel et l'obtention de coupes sériées de 7 μm d'épaisseur, rend possible la détection d'un petit nombre de mycoplasmes et l'étude de leur évolution dans la plante.

Sur matériel inclus dans les résines, les colorations polychromatiques (thionine — acridine orange en particulier) de coupes de 0,5 à 1 μm d'épaisseur, permettent de repérer les mycoplasmes avec beaucoup plus de précision que les colorations monochromatiques couramment utilisées jusqu'ici.

Mots clés additionnels : *Microscopie photonique, fluorochrome, paraffine, résine, coupe semi-fine, thionine, acridine orange, bleu de méthylène, azur A, safranine.*

I. INTRODUCTION

It is still quite difficult to identify plant mycoplasma diseases. The indexing methods using grafting, dodder or insect vectors are tedious and cannot be used in every case. Due to spontaneous recovery, tests using derivatives of tetracycline are sometimes difficult to apply. Specific and high titer sera are difficult to obtain with M.L.O.s. Transmission electron microscopy (T.E.M.), which is a cumbersome technique, permits only the investigation of a restricted area of the plant. Light microscopy methods under normal or fluorescent light are accessible to any laboratory. Recent advances in their specificity and accuracy have contributed to the wider use of such methods.

Initial work on the detection of yellows diseases was conducted using fluorescence microscopy without fluorochrome (COUSIN & GRISON, 1966 ; COUSIN *et al.*, 1968) or with fluorochromes non-specific for DNA or callose (CARLE, 1965). Altered areas could thus be detected in the phloem of the plant. However, no accurate information was provided on the presence of mycoplasmas. Use of aniline blue, a fluorochrome specific for callose at pH8 (ESCHRICH & CURRIER, 1964 ; HIRUKI & SHUKLA, 1973) showed this polysaccharide accumulation of on the walls of sieve tubes, within the intine of altered pollen grains, or in free state inside the pollen sacs (COUSIN, 1979, 1980).

Recent progress on DNA-specific fluorochromes such as D.A.P.I. (4-6 Diamidino 2 phenylindole) and

HOECHST reagent (bis-benzimidazole derivate) has raised increased interest in fluorescence microscopy. These fluorochromes were first used on animal cells (RUSSEL *et al.*, 1975 ; BONISSOL *et al.*, 1978), then on plant material (SEEMÜLLER, 1976 ; CAZELLES, 1978 ; DOSBA & LANSAC, 1982 ; COUSIN & JOUY, 1983a,b).

Other DNA-specific fluorochromes (PETZOLD & MARWITZ, 1979a,b,c) can be used but provide no additional information as D.A.P.I. and HOECHST.

II. METHODS AND RESULTS

A. Utilization of HOECHST reagent

We compared the results obtained under blue and ultraviolet light on sieve tubes isolated by pectinase, on fresh or fixed plant material cut by freezing microtome and finally on material embedded in paraffin after fixation and dehydration. For the present study, we selected *Catharanthus roseus* both as a control and affected by stolbur.

UV light permitted easier observation than blue light. As a result, major additional fluorescence can be removed. Nevertheless, blue-light observation is complementary because it allows the better localization of fluorescent areas in all plant tissues.

The isolation of sieve tubes by pectinase, as described by CAZELLES (1978), was conducted on fresh material or material fixed by 3 % glutaraldehyde in cacodylate buffer 0.1 M at pH 7.2. This procedure gives more or less satisfactory results depending on the origin of the pectinase used.

The procedure of freezing sections of fresh or fixed material gave excellent results, confirming the work of DOSBA & LANSAC (1982). Fixatives derived from formalin should be discarded, whereas Carnoy's fluid as well as 3 % glutaraldehyde in cacodylate buffer 0.1 M at pH 7.2 proved to be satisfactory. This procedure, that can be handled more easily than Feulgen staining (KARTHA *et al.*, 1975), is much more accurate. Isolated particles can be detected.

Finally, similar fluorescence was obtained on material fixed as previously described, dehydrated, embedded in paraffin, then deparaffinized and gradually rehydrated (plate 1). The previously mentioned fixatives were satisfactory. However, glutaraldehyde seemed to preserve the tissues better than Carnoy's fluid. This finding is in agreement with the results of FEDER & O'BRIEN (1968) who recommend the use of non-coagulant fixatives such as osmium tetroxide, acrolein, glutaraldehyde or formaldehyde. The accuracy of the results obtained on paraffin-embedded material was improved by thinner sections (7 to 10 μ m) and by the possibility of obtaining serial sections. Isolated (a), concentrated (b) and degenerated (c) MLOs could be detected (plate 1). In addition, the material could be permanently preserved.

However, the procedures based on HOECHST reagent and D.A.P.I. showed some limitations. They provided information solely on DNA, but not on the nature of the pathogen (mycoplasma, bacterium or DNA virus). Besides, they were not suitable for material embedded in the resins commonly used in T.E.M. such as epon, araldite or Spurr's mixture. Adjacent

sections fixed simultaneously can be observed successively under light and electron microscopy (DOSBA & LANSAC, 1982), but the investigation cannot be carried on within one block. Therefore, it seems that histochemical procedures on semi-thin sections should be improved simultaneously with the above procedures using fluorescence microscopy.

B. Use of polychromatic stains for improving staining procedures on semi-thin sections (COUSIN & JOUY, 1983)

Usually, the presence of resin is considered to be a major obstacle to the penetration of histochemical stains. Unfortunately, the resin can be removed only by procedures that denature the cell. Satisfactory results obtained with such stains on semi-thin sections embedded in resin are being increasingly reported, whereas research work on the removal of resins does not seem to produce the positive results expected.

We selected two staining procedures which proved to be effective on semi-thin sections embedded in resin : first, thionin and acridine orange (PAUL, 1980) and secondly, methylene blue-azure A and safranin (WARMKE & LEE, 1976).

1. Thionin and acridine orange (PAUL, 1980)

Solution A : Thionin

Thionin	0.5 g
Distilled water	200 ml
NaOH 0.1 N	50 ml
90 % ethanol	250 ml

Solution B : Acridine orange

Acridine orange	6.25 g
Distilled water	200 ml
NaOH 0.1 N	50 ml

Staining was carried out using warming plate at 45 °C. The slide was covered with solution A for 10 min, rinsed with distilled water, dried on the warming plate, and then covered with solution B for 2 min. Finally, the section was mounted in the resin that had been previously used for embedding the samples.

2. Methylene blue-azure A and safranin (WARMKE & LEE, 1976)

Solution A : Methylene blue-azure A

Methylene blue	0.13 g
Azure A	0.02 g
Glycerol	10 ml
Methanol	10 ml
Phosphate buffer 0.1 M, pH 6.9	30 ml
Distilled water	50 ml

Solution B : Safranin

Safranin	0.1 g
Tris buffer 0.2 M, pH 9.0	100 ml

The slides were dipped in solution A for 30 min at 60 °C, rinsed thoroughly with distilled water, immersed in solution B at 60 °C, rinsed with running water, then with distilled water and dried on the warming plate set at 60 °C. After 3 successive xylene baths,

they were mounted in the same resin used for embedding.

Both thionin and methylene blue-azure A stained

MLO, nucleoplasm, nucleolus and cytoplasm differentially, whereas acridine orange and safranin allowed the detection of wall constituents (table 1).

TABLE 1

Colour reactions of different forms of MLOs and host cell constituents with mono and polychromatic stains, using 0.5-1 µm semi-thin and resin embedded sections.

Observations de différentes formes de M.L.O. et d'éléments cellulaires de la plante-hôte, à la suite de colorations monochromatiques et polychromatiques réalisées sur des coupes semi-fines de 0,5-1 µm d'épaisseur dans les résines.

Mycoplasmas and cell constituents	Stains	Monochromatic	Polychromatic	
		Paragon	Thionin-acridine orange	Methylene blue azure A, safranin
Typical isolated (a) and concentrated (b) M.L.O.		pink	light purple	purple
degenerated (c) M.L.O.		dark red	dark purple	blue black
Nucleoplasm		light pink	light purple	purple
Nucleolus		dark pink	blue purple	blue purple
Cytoplasm		pink	purple	dark purple
Cellulose		red	yellow	red

In 0.5-1 µm thick semi-thin sections of material embedded in resin (epon and Spurr's mixture), mycoplasmas could be detected individually and followed in different stages (plate II). In one section several types of mycoplasmas could be observed: some MLOs (a) were scattered along the walls of the sieve tubes. Others (b) occurred in large numbers, but still scattered and individually distinct. Some degenerated MLOs (c) formed more intensely stained clusters.

Observations are summarized in table 1 that shows the advantage of polychromatic stains (thionin-acridine orange and methylene blue-azure A-safranin) as compared to monochromatic stains commonly used on semi-thin sections.

III. CONCLUSION

Fluorescence microscopy has made considerable progress over recent years. Presently it is the most rapid and specific method for identifying myco-

plasmas under light microscopy. Using this procedure on sections embedded in paraffin, it is now possible to store the samples and to improve the image obtained due to the thinness of the sections.

The present results concerning the use of polychromatic stains on semi-thin sections represent a preliminary step toward improving the methods devised for the examination of material embedded in resin, although these methods are more time-consuming than those using fluorescence and are not DNA-specific. They permit the observation of individual mycoplasmas, which was difficult with monochromatic stains, and they provide information suitable for confirming by electron microscopy. Such methods should be accessible to any laboratories with microtomes capable of sectioning either paraffin or resin. The blocks might then be sent on to electron microscopy laboratories for final identification.
