Zona-free hamster ovum penetration by human spermatozoa : influence of various sperm factors

Anne-Marie COURTOT, P. JOUANNET

Laboratoire d'Histologie-Embryologie-Cytogénétique.
Centre Hospitalier, 94270 Le Kremlin-Bicêtre, France.

Summary. The present paper evaluates the influence of various technical factors when preparing human spermatozoa to be tested for their ability to penetrate zona-free hamster ova. Higher *in vitro* fertilization rates were obtained after sperm selection by « swim-up » migration, 4-h incubation, sperm dilution to a concentration of 2.5×10^6 spermatozoa/ml, and observation of the oocytes 8 h after insemination. The use of control samples was necessary because of wide intraindividual and interindividual variations in the results. Unless the result has been confirmed several times, it is impossible to conclude, from a negative test, that a human spermatozoon cannot penetrate a hamster oocyte.

Introduction.

Mammalian fertilization needs intraspecific gamete recognition. However, some stages of sperm-ovum interaction seem to be analogous in heterospecific *in vitro* fertilization. In 1976, Yanagimachi *et al.* obtained swollen human sperm heads and male pronuclei in zona-free hamster oocytes and proposed using this procedure to evaluate human sperm fertilizing ability. The test has been reproduced by many authors (see review in Yanagimachi, 1984 ; Junca, 1984). However, the techniques of sperm preparation are so different from one study to another that it is very difficult to compare the results.

The present study investigated the influence of the sperm selection method, incubation and observation times, and sperm concentration and compared the results obtained using different ejaculates from the same men.

Material and methods.

Sperm preparation. — Semen samples were collected from 8 volunteers by masturbation at the laboratory. They were selected for the normal values of their semen parameters. Two were of proven fertility. After ejaculation, the samples were left 30 to 60 min at room temperature to allow liquefaction.

— Sperm washing : 5 ml of modified Biggers, Whitten and Whittingham (1971) medium (BWW) having an osmolarity of 410 mOsm/kg and containing 0.8 % of human serum albumin (fraction V, Sigma) were added to 1 ml of semen. The sperm suspension was centrifuged twice at $600 \times g$ for 5 min and resuspended in 1 ml of BWW.

— Sperm migration : 1.2 ml of BWW were layered over 1 ml of semen in a test-tube. Great care was taken to maintain an interface. The tube was placed in a 5 % CO₂, 20 % O₂, 75 % N₂, H₂O saturated atmosphere. After one hour, the upper 1 ml of the BWW fraction was gently removed by aspiration.

— Incubation : the spermatozoa prepared with either method were allowed to incubate at 37 °C in modified BWW in a 5 % CO₂, 20 % O₂, 75 % N₂, H₂O saturated atmosphere for 4 h. They were diluted to a final concentration of 2.5×10^6 or 0.5×10^6 spermatozoa/ml, depending on the method, and then put in contact with the oocytes.

Oocyte preparation. — Female golden hamsters were induced to superovulate by intraperitoneal injection of 30 IU of pregnant mare gonadotropin (PMSG, Sigma) on day 1 and 30 IU of human chorionic gonadotropin (hCG, Organon) on day 3. Sixteen to 18 h after hCG administration, the animals were sacrificed with ether. The oocytes were removed from the oviducts and placed in the culture medium. The cumulus and zona layers of the collected oocytes were removed by treatment in the medium with 0.1 hyaluronidase (Type I, Sigma) for 10 min and then with 0.05 % trypsin (Type I, Sigma) for about 2 min. After each enzyme treatment, the oocytes were washed 3 times in the culture medium.

Insemination. — Droplets of 200 µl each of sperm suspension were placed in sterile plastic dishes (Corning, 60 mm diameter). Approximately 20 zona-free hamster oocytes were added to each droplet and the mixture was incubated at 37 °C in a 5 % CO₂, 20 % O₂, 75 % N₂/H₂O saturated atmosphere. The zona-free oocytes were removed 3 and 8 h after insemination, washed 3 times in the medium, and observed under a microscope using phase or interferential contrast (1 000 \times Univar-Reichert).

Parameters studied. — Various images were observed : attached spermatozoa, swollen sperm heads, and male pronuclei (plate I, photos A, B, C). Further experiments on attached spermatozoa are needed. The human male pronucleus could be easily distinguished from the hamster female pronucleus by the presence of a tail. However, the tail does not always remain attached to the male pronucleus, and the female pronucleus may be fragmented (Yanagimachi, 1984) making interpretation difficult. Therefore, we used only ova in which the swollen sperm heads were clearly visible in the egg ooplasm.

PLATE 1. — *Interaction of human spermatozoa and zona-free hamster ova.*

A : Most of the spermatozoa are attached to the oocyte membrane (F) ; some of them have penetrated the cytoplasm and present a swollen head (SW). Interferential contrast $\times 1\,000$.

B : A pronucleus in the ooplasm. Interferential contrast $\times 1\,000$.

C : Pronuclei in the ooplasm. Probably resulting from the fragmentation of an initial pronucleus. Interferential contrast $\times 1\,000$.

Statistical analysis. — Sperm preparation methods, incubation times and sperm concentrations were statistically analysed using Student's t-test on paired data from each subject. For comparing the observation times, we used the Bartlett test (Snedecor and Cochran, 1971).

Results.

Influence of sperm characteristics. — The mean characteristics of the semen samples used in this study were : volume 3.3 ± 1 ml ; motility 53 ± 11 % ; vitality 83.8 ± 7 % ; concentration $126 \pm 38 \times 10^6$ ml. We did not find any correlation between the initial percentage of motile spermatozoa or sperm concentration and the percentage of oocytes with swollen sperm heads (25 ejaculates).

Influence of the sperm selection method. — In 14 samples, we compared the percentages of oocytes penetrated by migrated spermatozoa (2.5×10^6 cells/ml) and washed spermatozoa (2.5×10^6 cells/ml) after 4 h of incubation. Since a significantly higher rate of penetrated oocytes was obtained in the « swim-up » population (51 vs 26 % ; $P < 0.001$) we retained this preparation method for a study of the other factors.

Influence of sperm concentration. — The penetration ability of 0.5×10^6 and 2.5×10^6 inseminated spermatozoa per ml was evaluated in six different samples after 4 h of incubation. Although better results were obtained with 2.5×10^6 cells/ml, the difference was not significant after either 3 or 8 h (fig. 1).

FIG. 1. — Influence of the concentration of inseminated spermatozoa on the percentage of penetrated hamster oocytes (mean \pm SEM) 3 or 8 h after insemination.

■ = 0.5×10^6 spermatozoa/ml ;
□ = 2.5×10^6 spermatozoa/ml.

Influence of incubation time. — The influence of incubation time was tested in 11 semen samples from 5 men. In all cases, the number of penetrated oocytes was significantly higher (37 vs 8 % ; $P < 0.01$) after 4 h of incubation compared to 0 h, i.e. when the spermatozoa were inseminated immediately after « swim-up » migration in BWV.

Influence of observation time. — In 35 semen samples from 7 men (3 to 8 for each man), we tested the influence of the time-lag between insemination and the time the oocytes were analysed. Incubation time was 4 h in all cases.

The results varied among the subjects as shown in figure 2. In 3 cases (subjects 1, 3 and 6), the mean percentages of penetrated oocytes did not exceed 50 % 3 and 8 h after insemination, and the results were not significantly different between the two observation times. In 2 cases (subjects 4 and 7), the percentages of penetrated oocytes were high as early as 3 h after insemination. In the last 2 cases (subjects 2 and 5), there was a marked increase in the percentages of penetrated oocytes at 8 h.

FIG. 2. — Influence of observation time after insemination on the percentage of penetrated hamster oocytes (mean \pm SEM).

Numbers over bars indicate the mean number of swollen sperm heads per penetrated oocyte.

▨ = 3 h after insemination ; □ = 8 h after insemination.

Although some of the swollen sperm heads might have been transformed into pronuclei as late as 8 h after insemination, the mean percentage of oocytes with decondensed sperm heads did not decrease. In all cases but 2 (subjects 2 and 5), the mean number of swollen sperm heads per ovum was the same regardless of the time of observation.

Reproducibility of the test with various semen samples from the same donor. — In most cases, large variations in the percentages of penetrated oocytes were observed in different semen samples from the same subject (table 1). If we consider 20 % as the lowest limit of a positive test, as is generally the case (Hall, 1981) only 3 subjects always showed a positive test. In one case (subject 2), the test was always negative 3 h after insemination but positive 8 h after. The sperm from 3 men (subjects 1, 3 and 6) gave variable results.

TABLE 1

Variation in the % of penetrated oocytes observed with spermatozoa from the various ejaculates of 7 men. The test was positive if more than 20 % of the oocytes were penetrated.

Subject number	Observation 3 h	After insemination	Observation 8 h	After insemination
	% of penetrated oocytes (Range)	Number of positive tests	% of penetrated oocytes (Range)	Number of positive tests
1	3- 41	3/8	0- 77	2/8
2	0- 10	0/5	64- 95	3/3
3	0- 29	1/5	4- 40	4/5
4	28-100	8/8	71-100	7/7
5	23- 70	4/4	46- 98	4/4
6	5- 68	1/5	12- 43	3/5
7	60- 80	3/3	64- 82	3/3

Discussion.

Human spermatozoa must be removed from the seminal plasma before their ability to penetrate zona-free hamster oocytes can be tested. In most cases, this procedure combines centrifugation and dilution of the pellet in the culture medium, leading to an unselected population of sperm cells. Some authors select motile spermatozoa by their active « swin-up » migration from the seminal plasma to the culture medium (Barros *et al.*, 1979 ; Gould *et al.*, 1983 ; Pilikian, 1983 ; Tyler *et al.*, 1981 ; Wolf and Sokolski, 1982). With this method the conditions are comparable to the physiological situation in which spermatozoa have to move actively through the cervical mucus before reaching the oocytes. Mortimer *et al.* (1984) have shown that « swim-up » migration increases the percentage of motile cells. The results obtained here confirm their findings. We also observed a morphological selection of spermatozoa after migration, the mean percentage of normal cells being 78 (67 to 93) vs 59 (47 to 74) in the semen. Such selection is also known to occur in the cervical mucus (Jeulin *et al.*, 1984). Since the oocyte penetration rate was higher when « swin-up » migration was used to select the spermatozoa, we found this method more suitable for the test.

The penetration rate was related to the concentration of spermatozoa put in contact with the oocytes. Binor *et al.* (1980) found that the number of incorporated spermatozoa was expressed as a function of the log of the concentration of motile spermatozoa for concentrations ranging from 6×10^5 to 5×10^6 /ml. According to Tyler *et al.* (1981), the rate of oocytes penetrated by spermatozoa prepared by « swim-up » migration was not influenced by sperm concentrations of 1×10^6 to 8×10^6 /ml. Using unselected spermatozoa, Martin and Taylor (1983) observed a decrease in the penetration rate at a sperm concentration of 5×10^5 /ml. Using selected and mainly motile spermatozoa at a concentration of 2.5×10^6 cells/ml, we observed a good penetration rate of 55.1 %. Our experimental conditions were optimal (penetration rate : 100 %) in only some cases of the studied population, but with this concentration the number of spermatozoa attached to the oocyte membrane did not prevent the investigator from clearly observing the nuclear decondensation of incorporated spermatozoa so that comparative studies could be carried out.

The mean penetration rate was lower at a sperm concentration of 0.5×10^6 /ml as compared to a sperm concentration of 2.5×10^6 /ml (31.9 vs 55.1 %). This must be kept in mind, especially when testing spermatozoa swimming up with low efficiency, as shown for instance in human spermatozoa lacking outer dynein arms (Courtot *et al.*, 1984).

Modified BWW medium with an osmolarity of 410 mOsm was used in this study. Aitken *et al.* (1983) have shown that the use of this medium improves the acrosome reaction and the percentage of penetrated zona-free hamster oocytes, and they recommended a total assay time of 6 h for routine use. Higher penetration rates could be obtained with longer incubation times (Johnson and Alexander, 1984). However, no study has been carried out using an hyperosmotic medium.

With a modified BWW medium supplemented with 0.8 % human serum albumin, we found a significantly higher penetration rate when the incubation time was 4 h and the observation time after insemination 8 h as compared to 0 and 3 h, respectively. Nevertheless, in some cases the penetration rate was 20 % as early as 3 h after insemination. Our results support those of Perreault and Rogers (1982) who showed that the spermatozoa required a certain time for capacitation and that that time varied with the subject.

Test reliability has been studied by several authors (Binor *et al.*, 1980 ; Cohen *et al.*, 1982 ; Hall, 1981 ; Junca *et al.*, 1982 ; Karp *et al.*, 1981 ; Tyler *et al.*, 1981 ; Zausner-Guelman *et al.*, 1981). Rogers *et al.* (1983) distinguished men whose spermatozoa penetrated hamster oocytes at a constant (high or low) rate from those men whose penetration rate varied. Our study confirms these results. The penetration rate (independent of incubation and observation times) was higher than 20 % in all the ejaculates of only 3 of the 7 men studied. Intra-individual variations depended on factor(s) unknown to us since we could not find any explanation related to sperm characteristics or to female factors ; in our experiment, the oocytes from different animals were pooled in order to avoid any distortion related to the penetration rate due to variations in oocyte quality. Besides, intra-assay variability has already been studied by Tyler *et al.* (1981).

For a valid interpretation of the results and from a practical viewpoint, technical factors should be taken into consideration, particularly when spermatozoa lacking outer dynein arms are tested ; the low percentage of penetrated hamster oocytes may be related to a low concentration of migrated spermatozoa. It is impossible to conclude from one negative test that a human spermatozoon is unable to penetrate an oocyte ; it has to be confirmed several times.

Conclusion.

The selection of spermatozoa by « swim-up » migration, 4-hour incubation, observation of the oocytes 8 h after insemination, reproducibility of the procedure and the use of control samples seem to be good criteria for testing the ability of human spermatozoa to penetrate zona-free hamster oocytes at a concentration of 2.5×10^6 spermatozoa/ml. Should these factors be modified, especially in the case of pathological samples, great care must be taken in interpreting the results.

Résumé. *Pénétration de spermatozoïdes humains dans les ovocytes dépellucidés de hamster. Etude de différents facteurs spermatiques.*

Nous avons mesuré l'influence de différentes conditions techniques de préparation du sperme sur la capacité de pénétration des spermatozoïdes humains dans les ovocytes dépellucidés de hamster. De meilleurs résultats ont été obtenus par migration ascendante et incubation pendant 4 heures lorsque l'on utilise des spermatozoïdes humains à la concentration de $2,5 \times 10^6/\text{ml}$. L'utilisation de spermes témoins est nécessaire du fait de la variabilité intra et inter-individuelle des résultats. Il n'est pas possible d'affirmer que le sperme d'un sujet donné est incapable de pénétrer dans les ovocytes de hamster à partir d'un résultat négatif à moins qu'il n'ait été confirmé plusieurs fois.
