Summary. The relationship between the nature of *in vitro* digestion products and protein quality evaluation in rats was established. Eleven protein sources of animal and vegetable origin and of various purities were digested by pepsin then by pancreatin in a dialysis bag of 1 000 molecular weight cutoff. Animal proteins were generally better digested *in vitro* than vegetable proteins. Amino acid release partly reflected enzyme specificity and varied depending on the nature of the protein. Essential amino acids were generally released rapidly at the expense of non-essential amino acids. The composition of protein hydrolysis products was thus markedly different from that of the protein before digestion. Digestibility determination in rats showed much less variation between proteins than the *in vitro* method ; the two digestibility measurements did not correlate. However, by using stepwise multiple regression analysis, the amino acid composition of *in vitro* digestion products was found to correlate with the protein efficiency ratio (PER) more accurately than protein composition ($R^2 = 0.981$ and 0.934 , respectively). A regression analysis with net protein ratio (NPR) gave lower R^2 coefficients than with PER (0.941 and 0.921 , respectively). When regression equations were employed to predict the PER and digestion products were used instead of protein composition, an improvement was seen for almost all the test proteins, especially beef, rapeseed and wheat gluten. Better evaluation of protein quality by the use of protein digestion products demonstrates the possible impact of amino acid availability on protein quality.

Introduction.

The nutritional quality of a protein is primarily related to its amino acid composition. However, amino acid availability is also a key factor of protein quality. Availability depends on the process of digestion, which may be affected by many factors such as the characteristics of the protein itself (Silano, 1976 ; Stahmann

⁽¹⁾ Contribution No 13 from « Centre de Recherche alimentaire de Saint-Hyacinthe, Direction de la Recherche, Agriculture Canada, Saint-Hyacinthe, Québec, Canada, J2S 4Z4.

and Woldegiorgis, 1975), the presence of anti-nutritional factors (Green and Nasset, 1983 ; Liu, Means and Feeney, 1971), or interactions with other components of the foodstuff such as carbohydrates (Forsum, 1975 ; Bloomgarden *et al.*, 1981). One or more of these factors can be positively or negatively influenced by food processing.

Assays combining enzymatic hydrolysis with amino acid analysis attempt to evaluate the availability of individual amino acids since they provide data on how much of each is released from the protein. Different systems consisting of one or several enzymes in one or more steps were developed (Stahmann and Woldegiorgis, 1975 ; Sheffner, Eckfeldt and Spector, 1956 ; Buchanan, 1969). The major limitations of these methods are the lack of a suitable way of separating the digestion products from the digesta and, eventually, their incapacity to reproduce *in vivo* digestion.

Gauthier *et al.* (1982) developed an *in vitro* digestion method based on the original approach of Mauron *et al.* (1955) which considerably reduced the above-mentioned drawbacks. It consisted of pepsin digestion of the protein followed by enzymatic hydrolysis with pancreatin. The latter step was carried out in a highly selective dialysis bag with a 1 000 molecular weight cutoff for the simultaneous selection and removal of digestion products by a circulating dialysis buffer. The design and flow parameters of the digestion apparatus were modified and a « digestion cell » with a high analytical capacity and better accuracy and reproducibility was developed (Savoie and Gauthier, 1986). The enzymatic parameters of the method were reevaluated and adjusted (Gauthier, Vachon and Savoie, 1986).

The purpose of the present work was to examine the degree of correspondence of this method with the *in vivo* situation. Eleven different protein sources were digested in the digestion cell and the data were correlated with the *in vivo* nutritional evaluation of proteins in rats : protein efficiency ratio (PER), net protein ratio (NPR) and apparent digestibility.

Material and methods.

Animals and diets. — PER and NPR were measured according to Pellett and Young (1980) using male Sprague-Dawley rats (Canadian Breeding Farm, St-Constant, Québec). The rats were housed individually in mesh-bottomed cages under controlled conditions (24 °C, 50 % humidity, lights-on between 07 and 19 h). Upon arrival, they were fed a non-purified diet (Purina Rat Chow, Ralston Purina, St-Louis, MO) with water *ad libitum* for 3 days. After that, the rats (mean body weight : 70.5 ± 0.5 g) were divided into twelve groups of ten each and fed *ad libitum* purified diets containing 10 % crude protein (table 1) for 28 days. A protein-free diet containing 854 g of corn starch, 50 g of cellulose and all the basal ingredients was given to group 12 for 10 days and used to measure the NPR. Food was replaced every other day. Food consumption for the period was recorded after correction for spillage. Stools were collected from day 6 to day 10

included and apparent digestibility was calculated relative to Cr_2O_3 (Christian and Coup, 1954) as a non-absorbable marker using the following equation :

$$\text{digestibility (\%)} = 100 - 100 \left(\frac{\text{Cr diet}}{N} \div \frac{\text{Cr stools}}{N} \right).$$

Nitrogen was determined by an automated Kjeldahl method (Model 16210 Kjell-Foss Autoanalyzer, Foss Co., Denmark).

TABLE 1

Crude protein content of protein sources and diet composition on a kg basis (1).

Protein sources	% Protein (N \times 6.25)	Quantity used in the diets (g)		
		Protein	Corn starch	Cellulose ⁽²⁾
Egg ^(3,4)	70.2	142.5	626.3	86.2
Lactalbumin ⁽⁵⁾	84.8	117.9	655.6	81.5
Beef ^(3,4)	85.6	116.8	674.6	63.6
Rapeseed ⁽⁶⁾	67.0	149.3	651.0	54.8
Casein ICN ⁽⁵⁾	87.8	113.9	686.1	55.1
Casein ANRC ⁽⁷⁾	92.5	108.1	691.4	55.5
Soybean ⁽⁵⁾	67.5	148.1	652.1	54.7
Oatmeal ⁽⁴⁾	17.4	574.7	151.5	128.3
Peanut meal ⁽⁵⁾	47.3	211.4	581.5	62.1
Wheat flour ⁽⁴⁾	16.0	625.0	187.5	42.5
Wheat gluten ⁽⁵⁾	82.5	121.5	654.2	79.6

(1) Other ingredients per kg diet were : a) 100 g of corn oil ; b) 1 g Cr_2O_3 ; c) 35 g of Mineral Mix (AIN-76, ICN Nutritional Biochemicals, Cleveland, OH) (13) ; d) 10 g of vitamin mixture (Vitamin Fortification Mixture, Teklad, Madison, WI), supplying in mg/kg diet : retinyl palmitate, 39.7 (19,850 μ), ergocalciferol, 4.4 (2 200 μ), α -tocopheryl acetate, 485 (121 μ), ascorbic acid, 987, 1-inositol, 110.2, choline dihydrogen citrate, 3 715, menadione, 49.6, p-aminobenzoic acid, 110.2, niacin, 99.2, riboflavin, 22, pyridoxine HCl, 22, thiamin HCl, 22, calcium pantothenate, 66.1, biotin, 0.44, folic acid, 1.98, vitamin B₁₂, 29.8.

(2) Alphacel (non nutritive bulk, ICN).

(3) Ether extract of the freeze-dried product.

(4) Purchased from a local dealer. Beef was sirloin steak.

(5) ICN Nutritional Biochemicals, Cleveland, OH.

(6) Low glucosinolate rapeseed protein prepared by FRI-75, a process from the food Research Institute, Agriculture Canada, Ottawa (a generous gift).

(7) Animal Nutrition Research Council, ANRC (Sheffields Products, Memphis, TE).

Diet composition is given in table 1. The protein sources were of different purity : the two caseins, lactalbumine and wheat gluten were obtained as purified protein sources, while the others were partially purified either in the laboratory (egg and beef) or by the dealer (rapeseed, soybean, oatmeal, peanut meal and wheat flour). In order to keep a constant protein : energy ratio among the diets, the energy content of the diet components was measured by bomb calorimetry (Parr Adiabatic Calorimeter, Moline, IL) ; corn starch served to adjust gross energy at 4.06 Kcal/g and cellulose was used as a filler. For example, it was necessary to reduce corn starch in the oatmeal diet and to add non-nutritive cellulose as a filler because the energy density of this protein source was high and much was needed in the diet to obtain a 10 % protein level.

***In vitro* digestion with dialysis.** — The protein sources were digested according to the method of Gauthier, Vachon and Savoie (1986), *i.e.* 30 min digestion of 250 mg of protein ($N \times 6.25$) with 1 mg of pepsin (1 : 600, Sigma, St-Louis, MO) at 37 °C in 0.1 N HCl adjusted to pH 1.9 with N NaOH ; the mixture was then digested at pH 7.5 with 10 mg of pancreatin (5X, ICN) at 37 °C in a « digestion cell » (Savoie and Gauthier, 1986) as follows : the reaction was carried out in a dialysis bag of 1 000 molecular weight cutoff for the simultaneous selection and removal of the digestion products in a 10 mM sodium phosphate buffer, pH 7.5. The buffer was pumped through the digestion cell at a rate of 1.6 ml/min by a peristaltic pump. Samples of the dialysate (digested material) were collected every hour for 6 h and stored at – 20 °C for nitrogen determination by an autanalyzer (method No. 329-74 W/B from Technicon Instruments, Tarrytown, N.Y.) and for amino acid analysis. To obtain the protein and amino acid digestibilities of table 3, the pool of the six time samples was analysed. Pancreatin was a crude preparation containing all the pancreatic enzymes ; trypsin and chymotrypsin activities were measured giving 2.2 TAME units and 4.1 ATEE units, respectively, per mg of protein (Gauthier, Vachon and Savoie, 1986).

Crude protein and amino acid digestibilities (%) after 6 h of digestion with pancreatin were calculated from the following equations :

$$\text{Crude protein digestibility} = \frac{\text{quantity of N recovered in the dialysate}}{\text{quantity of N used in the assay}} \times 100$$

$$\text{Amino acid digestibility} = \frac{\text{quantity of a given amino acid recovered in the dialysate}}{\text{content of the amino acid in the test protein sample}} \times 100$$

Amino acid analysis. — Acid hydrolysis of either the protein sources or the dialysate was performed according to Simpson *et al.* (1976). Two mg of the protein were suspended in vacuum tubes in 1 ml of 4 N methanesulfonic acid with 0.2 % 3-(2 aminoethyl) indole added (Vacuum reaction tubes, Pierce, Rockford, IL). Gaseous nitrogen was flowed into the tubes for 2 min to remove the air and the tubes were frozen in a mixture of liquid nitrogen and acetone. After a vacuum was created, the tubes were allowed to thaw slowly. This procedure was repeated once. Hydrolysis was carried out at 110 °C for 24 h ; the hydrolysate was then partially neutralized with 1 ml of 3.5 N NaOH and filtered successively through Whatman No. 1 and 0.22 µm Millipore filters. The internal standard (0.2 µmole norleucine) was added before hydrolysis. Amino acid analysis was performed by ion-exchange chromatography (Model 4 000 autoanalyzer, LKB Instruments, Rockwell, MD). The tryptophan content of oatmeal, peanut meal and wheat flour were not recorded because appreciable losses occur with methane-sulfonic acid hydrolysis when the protein samples contain more than 20 % carbohydrates (Simpson *et al.*, 1976).

Statistical analysis. — *In vivo* data and crude protein *in vitro* digestibility were submitted to an analysis of variance and evaluated with Duncan's multiple-range test (Duncan, 1955). The relationship between *in vitro* and *in vivo* data was esta-

blished by Pearson's correlation test and stepwise multiple regression analysis using a computerized system (SAS Institute, 1979).

Results.

Amino acid content of test proteins. — The great difference between the test proteins was their protein content (table 1) and amino acid profile (table 2). Sources of animal origin contained more protein than those of vegetable origin, with the exception of wheat gluten. Also, the essential amino acid content of the former proteins was higher. Methionine and cysteine contents were lower than reported values (Sarwar *et al.*, 1983). On the other hand, the fact that amino acids of both the protein sources and their digestion products were analysed using the same method minimized the possibility of bias in comparing the capacity of both amino acid profiles to predict protein quality.

(¹) Mean of five separate hydrolyses, except for oatmeal of which 4 determinations were made.

In vitro protein digestion. — Table 3 gives *in vitro* crude protein and amino acid digestibility after 6 h of pancreatic digestion. The enzymatic release of nitrogen was linear for 6 h, except for a short lag in the first jour of digestion (data not shown). Generally, proteins of animal origin gave better digestibility values than vegetable proteins, with the exception of peanut meal which was highly digestible, egg proteins which were poorly digested, and ANRC casein that was digested to the same extent as vegetable proteins.

Amino acid release varied mostly with the amino acid but also with the type of protein. Some amino acids were released rapidly from proteins while others were liberated more slowly. Generally, leucine, phenylalanine, tyrosine, lysine

(1) Quantity of material recovered in the dialysate \times 100/quantity of material used in the assay.

(2) Mean \pm SEM of five digestions, except for oatmeal of which 4 digestions were performed.

(3) Values (N digestibility only) with a different letter are significantly different ($P \leq 0.05$).

methionine, arginine and tryptophan were released rapidly. Others like threonine, aspartic acid, glutamic acid, and especially cysteine and proline, were liberated slowly. Essential amino acids were generally released more rapidly than non-essential ones.

The nature of the protein also influenced amino acid release. Among the rapidly released amino acids, the release of methionine, lysine and arginine of wheat proteins was very rapid ; however, the phenylalanine of these proteins was liberated more slowly than in other proteins. The release of the following amino acids was also notably rapid : methionine of soybean, tyrosine of egg, caseins and rapeseed, arginine of caseins, and tryptophan of all the proteins, except lactalbumin. However, lysine was liberated slowly in rapeseed protein, contrary to other proteins. Finally, the liberation of valine was low in beef and in casein ICN but high in peanut meal. With these differences in amino acid digestibilities, the composition of the digestion products differed markedly from that of the corresponding protein (table 4).

Nutritional evaluation in vivo. — The nutritional evaluation of the proteins, placed in decreasing order according to PER, is given in table 5. Food intake varied with the protein : animal proteins generally gave higher intakes than vegetable proteins, especially wheat proteins. Quality varied markedly with the protein. The PER of the poorest quality protein, wheat gluten, was only 10 % that of egg. Animal proteins had a higher nutritional value than vegetable proteins based on either PER or NPR, except for rapeseed protein whose quality was equivalent to that of casein. Corrected PER values (with ANRC casein fixed at 2.5 : Bieri *et al.*, 1977) are also given. NPR ranked ANRC casein higher than PER. NPR gave a higher nutritional value than PER to the poorest quality proteins, with wheat gluten having as much as 40 % of the nutritional value of egg proteins. The correlation between both tests using individual values was high ($R = 0.97$, $P < 0.001$). Apparent digestibility did not vary much with the protein source, since all values remained between 80 and 90 %. In spite of a good correlation with PER ($R = 0.34$, $P < 0.01$) and NPR ($R = 0.40$, $P < 0.003$), digestibility did not account for much of the variation in protein quality. It tended to be related to the purity of the protein source since it decreased with the protein content of the source.

Relationship between in vitro and in vivo data. — Evaluation of *in vitro* digestibility of nitrogen (6-hour digestibility of table 3) did not correlate with that of *in vivo* protein quality, R values being 0.05, - 0.01 and - 0.13, respectively, with PER, NPR and apparent digestibility. The use of amino acid composition to predict PER and NPR was tested by stepwise discriminant analysis using either the amino acid composition of the protein (C_0) (see table 2) or that of the *in vitro* digestion products (C_d) (see table 4). Table 6 gives the regression coefficients of PER and NPR with different amino acid combinations. With both C_0 and C_d , PER was calculated with a better degree of confidence when all the amino acids were taken together than when only the essential amino acids were used. The same held true when animal and vegetable proteins were taken separately, except for the PER of animal proteins computed with C_0 . Maximal R^2 values were obtained

(¹) Mean of 5 digestions analyzed separately for amino acids. Values for oatmeal are means of 4 digestions.

with all the amino acids when the vegetable proteins were taken separately ; in this situation, R^2 with C_0 and C_d was equivalent. However, when all the proteins were included in the test, C_d was slightly better than C_0 and gave a R^2 value that was almost as high as that obtained when the vegetable proteins were taken separately. NPR-calculated values were obtained with a lower degree of confidence than those of PER, except when the proteins were divided into two groups and the analysis made including essential amino acids only. PER (corrected) was calculated using C_0 or C_d with all the proteins and amino acids by the following equations :

$$\begin{aligned} \text{with } C_0, \text{ PER} &= 1.068 + 0.651 \text{ Thr} + 0.643 \text{ Val} - 0.558 \text{ Ile} \\ &\quad - 0.127 \text{ Leu} + 0.169 \text{ Lys} \\ \text{with } C_d, \text{ PER} &= 7.365 + 0.173 \text{ Asp} - 0.162 \text{ Ser} - 0.073 \text{ Glu} \\ &\quad - 0.185 \text{ Pro} - 0.212 \text{ Gly} - 0.190 \text{ Leu} + 0.166 \text{ Tyr} - 0.21 \text{ Arg} \end{aligned}$$

TABLE 5

(2) Mean ± SEM of 10 animals.

(3) Values with a different letter in the same column are significantly different ($P \leq 0.01$).

TABLE 6
Relationship between PER or NPR and amino acid composition of the proteins (C_0) or their in vitro digestion products (C_d).

	All amino acids		R^2	Essential amino acids	
	PER	NPR		PER	NPR
C_0 : all proteins	0.934	0.921		0.932	0.928
vegetable proteins	0.992	0.930		0.971	0.978
animal proteins	0.844	0.718		0.912	0.912
C_d : all proteins	0.981	0.941		0.912	0.897
vegetable proteins	0.990	0.941		0.974	0.985
animal proteins	0.928	0.880		0.760	0.877

These amino acids were those retained by the computer as being the discriminant ones by a stepwise procedure. Table 7 gives the PER-calculated values with C_0 and C_d and the difference from the corrected PER. Positive and negative differences were observed, depending on the protein source. Absolute differences of 0.3 or more were obtained for beef, rapeseed protein and wheat gluten when C_0 was used. A better calculation of PER was achieved with C_d since the differences did not exceed 0.09 and were generally lower than 0.05; the differences between measured- and calculated-PER values for the three proteins mentioned above, *i.e.* beef, rapeseed and wheat gluten, were then only 0.01, 0 and 0.07, respectively.

TABLE 7
PER-calculated values and the differences with the corrected PER using regression equations from either the amino acid composition of the protein (C_0) or that of the in vitro digestion products (C_d).

	With C_0		With C_d	
	Calculated values	Difference with corrected PER (¹)	Calculated values	Difference with corrected PER (¹)
Egg	3.06	- 0.01	3.06	- 0.01
Lactalbumin	2.77	0.00	2.77	- 0.00
Beef	2.90	0.32	2.59	0.01
Rapeseed	2.23	- 0.30	2.53	0.00
Casein ICN	2.35	- 0.18	2.44	- 0.09
Casein ANRC	2.48	- 0.02	2.51	0.01
Soybean	2.01	0.01	1.98	- 0.02
Oatmeal	1.98	0.01	1.93	- 0.04
Peanut meal	1.14	- 0.12	1.25	- 0.01
Wheat flour	0.77	- 0.05	0.85	0.03
Wheat gluten	0.67	0.35	0.39	0.07

(¹) Corrected PER values given in Table 5.

Discussion.

Test proteins were enzymatically digested *in vitro* in order to establish a relationship between the nature of *in vitro* digestion products and protein quality evaluated *in vivo*. The animal proteins generally showed better digestibilities than the vegetable proteins both *in vitro* and *in vivo*. One explanation is that the former contain more essential amino acids that are generally the specific targets of digestive enzymes (Fruton, 1971; Gray and Cooper, 1971). However, vegetable proteins contain more arginine, which could have obscured the above difference in digestibility between animal and vegetable proteins. For instance, peanut meal that had by far the highest arginine content was the most highly digested vegetable protein *in vitro*.

The non-protein components of a foodstuff are known to interfere with protein digestion (Silano, 1976). Apparent digestibility is generally inferior in proteins sources of low protein content such as most of the vegetable proteins tested in

this work. Contrarily, *in vitro* digestion was independent of the purity of the protein source, indicating that this type of digestion is more related to the protein itself than to its non-protein components.

Unlike *in vivo* digestibility, *in vitro* digestibility varied with the protein. The wider range of digestibility values obtained *in vitro* also resulted from the fact that digestion was intentionally stopped before it was completed. With a longer digestion time, it is conceivable that the difference in protein digestibility would level out, as has already been shown for amino acid release (Vachon *et al.*, 1983). The measurement of these parameters after a shorter digestion time provided a better discrimination of the proteins, even if it probably increased the variability of the *in vitro* measurements.

Raw egg protein was not well digested *in vitro*, probably due to the active enzyme inhibitors present in eggs (Liu *et al.*, 1971) and normally inactivated by heat (Silano, 1976). Our egg preparation was not heat-treated to prevent modification of the structure of the protein source. *In vivo*, the organism adapts to dietary enzyme inhibitors by increasing enzyme activities (Green and Nasset, 1983) so that digestion may be almost complete. However, in spite of the low extent of digestion, the composition of the digestion products of this protein still reflected its nutritional value.

It should be emphasized that apparent digestibility did not fully explain protein quality since the values ranged between 80 and 90 %. This would indicate that amino acid availability, instead of only nitrogen digestibility, must be considered when measuring protein quality. Amino acids released *in vitro* reflected digestive enzyme specificity (mostly pancreatic) and also the nature of the protein, as already observed by Vachon *et al.* (1982, 1983). Consequently, the amino acid composition of the digestion products was markedly different from that of the corresponding protein. The present finding illustrates the impact of digestion on the biological effects of proteins since C_d gave a better prediction of PER and NPR than C_0 . However, the non-protein components varied with the protein source. Since the values of the two growth tests might vary with this parameter, it is possible that their relationship with C_0 or C_d was also affected.

A high digestibility value *in vitro* was generally found for lysine, especially in cereals, while the availability of this amino acid is low *in vivo* (Darcy *et al.*, 1982 ; Sauer *et al.*, 1977). We believe that the *in vitro* data reflect a real biological process occurring at the very onset of digestion. This phenomenon could be compensated by intestinal absorption : the *in vitro* method thus provides a useful tool for investigating phenomena that are not detectable *in vivo*.

The increase of R^2 from 0.934 to 0.981 was relatively slight. However, not only the differences between measured PER and PER-calculated values were lower with C_d than with C_0 , but almost all the test proteins were improved (table 7). The correction was marked with vegetable proteins such as gluten or rapeseed that are often underevaluated by PER (Evans and Witty, 1978). When animal and vegetable proteins were separated into two sub-groups, the predictability of animal protein PER and NPR deteriorated. This may be because the range of nutritional values in this group was much narrower (corrected PER values from 2.50 to 3.07) than that of vegetable proteins (PER of 0.32 to 2.53).

Prediction precision was also reduced when the non-essential amino acids were excluded from the test. In fact, the PER was predicted better by an equation using a high positive constant that was reduced according to the content of some, mostly non-essential, amino acids. This finding indicated the importance of non-essential amino acids to protein quality, as indicated by other investigators (Sheffner *et al.*, 1980).

The relationship between *in vitro* and *in vivo* data was established using the most global *in vivo* approach, *i.e.* by measuring the final effect of amino acids on growth. The relationship was generally better with *in vitro* digestion products than with protein amino acid composition. Also, the correlation with the protein quality of some vegetable proteins was noticeably improved. Contrary to other procedures (Satterlee *et al.*, 1982), this can be interpreted as a correction for amino acid digestibility that the proposed *in vitro* method provides. This method can be applied to studies of variables likely to affect amino acid availability, such as alkaline or heat treatment, protein extraction or purification or anti-nutritional factors. However, the appropriateness of the method as a measurement of amino acid availability must be further evaluated by comparing *in vitro* digestion products with ileal digestibility of amino acids, their appearance in portal blood, and their utilization by the liver and peripheral tissues. These studies are currently in progress in rats and pigs.

Résumé. *Corrélation entre la digestion in vitro des protéines et leur évaluation nutritionnelle in vivo.*

La relation entre la nature des produits de digestion *in vitro* et l'évaluation nutritionnelle des protéines chez le rat a été examinée. Onze sources de protéines animales ou végétales, plus ou moins pures, ont été digérées avec de la pepsine, puis de la pancréatine dans un sac à dialyse d'exclusion moléculaire de 1 000. Généralement les protéines animales sont mieux digérées *in vitro* que les protéines végétales. La libération de chacun des acides aminés dépend de la spécificité des enzymes digestives et du type de protéine. Les acides aminés essentiels sont en général libérés plus rapidement que les acides aminés non essentiels. De ce fait, la composition des produits de digestion diffère fortement de celle de la protéine au départ. Dans nos conditions expérimentales, la digestibilité *in vitro* varie beaucoup plus d'une protéine à l'autre que la digestibilité mesurée chez le rat, de sorte que les deux mesures ne correspondent pas. Par contre, une analyse par régression linéaire multiple montre que le coefficient d'efficacité protéique (CEP) correspond un peu plus au profil en acides aminés des produits de digestion *in vitro* qu'à celui de la protéine, avec des R^2 respectivement de 0,981 et 0,934. L'analyse avec le coefficient protéique net donne une correspondance un peu plus faible avec des R^2 de 0,941 et 0,921. En utilisant les équations de régression en vue de prédire le CEP, l'amélioration qui est observée pour l'ensemble des protéines lorsque sont utilisés les produits de digestion plutôt que la composition de la protéine, est plus marquée pour certaines d'entre elles soit le bœuf, le colza et le gluten de blé. Ces résultats montrent une certaine incidence de la disponibilité des acides aminés dans la qualité nutritionnelle des protéines.
