Abstract

This paper presents PeerCube, a DHT-based system aiming at minimising performance penalties caused by high churn while preventing malicious peers from subverting the system through collusion. This is achieved by i) applying a clustering strategy to support quorum-based operations; ii) using a randomized insertion algorithm to reduce the probability with which colluding Byzantine peers corrupt clusters, and; iii) leveraging on the properties of PeerCube’s hypercube structure to allow operations to be successfully handled despite the corruption of some clusters. In spite of a powerful adversary that can inspect the whole system and issue malicious join requests as often as it wishes, PeerCube guarantees robust operations in $O(\log N)$ messages, with $N$ the number of peers in the system. Extended simulations validate PeerCube robustness.

1 Introduction

Research on the development of efficient peer-to-peer systems has recently received a lot of attention. This has led to the construction of numerous structured peer-to-peer overlays systems [16,24,19,9,14]. All these systems are based on distributed hash tables (DHTs) which partition an identifier space among all the peers of the system. Structured overlays enjoy numerous important properties. They are efficient, scalable, and tolerant to benign failures. However, less investigation has been carried out for handling both very high churn and collusive behaviour issues. As pointed out by Locher et al. [13], most proposed peer-to-peer overlays are highly satisfactory in terms of efficiency, scalability and fault tolerance when evolving in weakly dynamic environments. On the other hand, in the presence of very frequent connections/disconnections of peers, a very large number of join and leave operations are locally triggered engendering accordingly multiple and concurrent maintenance traffic. Ensuring routing tables consistency quickly becomes unbearable, leading to misrouting, and to possible partitioning of the system. The other fundamental issue faced by any practical open system is the inevitable presence of malicious peers [22]. Guaranteeing the liveness of these systems requires their ability to self-heal or at least to self-protect against this adversity. Malicious peers can devise complex strategies to prevent peers from discovering the correct mapping between peers and data keys. They can mount Sybil attacks [6] (i.e., an attacker generates numerous fake peers to pollute the system), they can do routing table poisoning (also called eclipse attacks [3,22]) by having good peers redirecting outgoing links towards malicious ones, or they can simply drop or re-route messages towards other malicious peers. They can magnify their impact by colluding and coordinating their behaviour.

This paper presents PeerCube, a DHT-based system aiming at avoiding high churn from impacting the performance of the system and at the same time at preventing malicious behaviour (coordinated or not) from subverting the system. As many existing DHT-based overlays, PeerCube is based on a hypercubic topology. PeerCube peers self-organise into clusters whose interconnections form the hypercubic topology. Peers within each cluster are classified into two categories, core members and spares, such that only the former ones are actively involved in PeerCube operations. Thus only a fraction of churn affects the overall topology of the hypercube. Defences against eclipse attacks are based on the observation that malicious peers can more easily draw a successful adversarial strategy from a deterministic algorithm than from a randomised one. We show that regardless of the adversarial strategy colluders employ, the randomised insertion algorithm we propose guarantees that the expected number of colluders in each routing table

*This work is partially supported by the CAPES / COFECUB program 497-05
is minimal. Furthermore, by keeping the number of core members per cluster small and constant, it allows to rely on the powerful consensus building block to guarantee consistency of the routing tables despite Byzantine peers. Finally, PeerCube takes advantage of independent and optimal length paths offered by the hypercubic topology to decrease exponentially the probability of encountering a faulty peer with the number of independent paths $O(\log N)$.

To summarise, PeerCube brings together research achievements in both “classical” distributed systems and open large scale systems (Byzantine consensus, clustering, distributed hash tables) so that it efficiently deals with collusion and churn. To the best of our knowledge this work is the first one capable of tolerating collusion by requiring for each lookup, put, join and leave operation $O(\log N)$ latency and only $O(\log N)$ messages.

In the remaining of the paper, we discuss related work in Section 2 and then present the system and adversary models in Section 3. Description of the architecture is given in Section 4 together with an analysis of the churn impact. Robustness against malicious behaviours (coordinated or not) is studied in Section 5. Results of simulations are presented in Section 6. We conclude in Section 7.

## 2 Related Work

In the following, we first review related work that focuses on robustness against malicious peers and then examine policies to handle high churn.

Regarding robustness to malicious behaviour, different approaches have been proposed, each one focusing on a particular adversary strategy. Regarding eclipse attacks, a very common technique, called constrained routing table, relies on the uniqueness and impossibility of forging peers' identifiers. It consists in selecting as neighbours only the peers whose identifiers are closer to some particular points in the identifier space $\mathbb{B}$. Such an approach has been successfully implemented into several overlays (e.g., CAN, Chord, Pastry). More generally, to prevent messages from being misrouted or dropped, the seminal works on DHT routing security by Castro et al. [3] and Sit and Morris [22] combine routing failure tests and redundant routing as a solution to ensure robust routing. Ravoaja and Anceaume extended this approach to cope with colluders by constraining the result of a query, which guarantees to reach the legitimate recipient with high probability $O(\log^2 N)$. However, in both approaches, the topological properties of their overlay do not guarantee that redundant paths are independent. Fiat et al. [17] use the wide paths technique initially proposed by Hildrum and Kubiatowicz [10]. All these solutions require all DHT nodes to maintain $O(\log^2 N)$ links to other nodes, and require for each operation $O(\log^3 N)$ messages.

With regard to churn, Li and al. [12] show through a comprehensive performance evaluation that structured overlays (such as Tapestry, Chord, or Kademia) can achieve similar performance with regard to churn if their parameters are sufficiently well tuned. However, these protocols do not focus on reducing the frequency at which routing tables are updated. Such an approach has been proposed in the eQuus architecture [13], in which nodes which are geographically close to each other are grouped into the same cliques to form the vertices of the hypercube. EQuus offers good resilience to churn and good data availability, however relying on local awareness to gather peers within cliques makes this architecture vulnerable to adversarial collusion and geographically correlated failures.

## 3 Model

### 3.1 System Model

Peers are assigned unique random identifiers from an $m$-bit identifier space when they join the system. Identifiers (denoted ID) are derived by using the standard MD5 hash function [18], on the peers’ network address. We take the value of $m$ large enough to make the probability of identifiers collision negligible. Each application-specific object, or data-item, of the system is assigned a unique identifier, called key, selected from the same $m$-bit identifier space. Each peer $p$ owns a fraction of all the data items of the system. Regarding timing assumption, we assume an asynchronous model. Rational of this assumption is that it makes difficult for malicious peers to devise strategies that could have been exploited in a synchronous timing model, such as DoS attacks [15].

### 3.2 Adversary Model

Some peers try to manipulate the system by not following the prescribed protocols and by exhibiting undesirable behaviours. Such peers are called malicious. Malicious peers can drop messages or forward requests to illegitimate peers. Malicious peers may act independently or may be part of a collusion group. A peer which always follows the prescribed protocols is said to be correct. We assume that there exists a fraction $\mu$, $0 \leq \mu < 1$, of malicious peers in the whole system. Malicious peers are controlled by a strong adversary. The adversary can issue join requests for its malicious peers in an arbitrary manner. At any time it can inspect the whole system and make its malicious peers re-join the system as often as it wishes. We assume the existence of a public key cryptography scheme that allows each peer to verify the signature of each other peer. We also assume that correct peers never reveal their private keys. Peers IDs and keys are part of their hard coded state, and are acquired via a central authority [5]. When describing the pro-
tocols, we ignore the fact that messages are signed and recipients of a message ignore any message that is not signed properly. We also use cryptographic techniques to prevent a malicious peer from observing or unnoticeably modifying a message sent by a correct peer. However a malicious peer has complete control over the messages it sends and receives. Note that messages physically sent between any two correct peers are neither lost nor duplicated.

4 Architecture Description

As discussed before, our architecture is based on a hypercubic topology. The hypercube is a popular interconnection scheme due to its attractive topological properties, namely, low node degree and low network diameter. Beyond these properties, a hypercube offers two important topological features, namely recursive construction and independent paths.

4.1 Background

This section presents some preliminaries related to the hypercubic topology. For more details the reader is invited to read Saad and Schultz [20]. A $d$-dimensional hypercube, or $d$-hypercube for short, consists of $2^d$ vertices, where each vertex $n$ is labelled by its $d$-bits representation. Dimension $d$ is a fundamental parameter since it characterises both the diameter and the degree of a $d$-hypercube. Two vertices $n_0 \ldots n_{d-1}$ and $m_0 \ldots m_{d-1}$ are connected by an edge if they share the same bits but the $i$th one for some $i$, $0 \leq i < d$, i.e. if their Hamming distance $H(n,m)$ is equal to 1. In the following, the notation $n = n' \uparrow i$ stands for two vertices $n$ and $m$ whose labels differ only by their bit $i$.

Property 1 (Recursive Construction [20]). A $d$-hypercube can be constructed from lower dimensional hypercubes.

The construction consists in joining each vertex of a $(d-1)$-hypercube to the vertex of the other $(d-1)$-hypercube that is equally labelled, and by suffixing all the labels of the vertices of the first $(d-1)$-hypercube with 0 and those of the second one with 1. The obtained graph is a $d$-hypercube. From this construction, we can derive a simple distributed algorithm for building a $d$-hypercube from a $(d-1)$ one which involves only 2 messages per link updated whatever the dimension of the considered system, and thus has a message complexity of $O(d)$ per peer.

Property 2 (Independent Routes [20]). Let $n$ and $m$ be any two vertices of a $d$-hypercube. Then there are $d$ independent paths between $n$ and $m$, and their length is less than or equal to $H(n,m) + 2$.

Two paths are independent if they do not share any common vertex other than the source and the destination vertices. In a $d$-hypercube, a path from vertex $n$ to vertex $m$ is obtained by crossing successively the vertices whose labels are obtained by modifying one by one $n$’s bits to transform $n$’s label into $m$’s one. Suppose that $H(n,m) = b$. Then $b$ independent paths between $n$ and $m$ can be found as follows: path $i$ is obtained by successively correcting bit $i$, bit $i + 1$, ..., bit $(i + b - 1)$ mod $b$ among the $b$ different bits between $n$ and $m$. Note that these $b$ paths are of optimal length $H(n,m)$. In addition to these paths, $d - b$ paths of length $H(n,m) + 2$ can be constructed as follows: path $j$ of length $H(n,m) + 2$ is obtained by modifying first bit $j$ on which $n$ and $m$ agree, and then by correcting the $b$ different bits according to one of the $b$ possibilities described previously, and finally by re-modifying bit $j$.

4.2 PeerCube in a Nutshell

We now present an overview of PeerCube features. Basically, our architecture has two main characteristics: peers sharing a common prefix gather together into clusters; and clusters self-organise into a hypercubic topology.

4.2.1 Clusters

As stated before, each joining peer is assigned a unique random ID from an $m$-bit identifier space. Assigning unique random IDs to peers prevents the adversary from controlling a portion of the network, since peers are spread wide over the network according to their identifier. Peers whose ID share a common prefix gather together within the same cluster. Each cluster is uniquely identified with a label that characterises the position of the cluster in the overall hypercubic topology. The label of a cluster is defined as the shortest common prefix shared by all the peers of that cluster such that the non-inclusion property is satisfied. The non-inclusion property guarantees that a cluster label never matches the prefix of another cluster label, and thus ensures that each peer in PeerCube belongs to at most one cluster.

Property 3 (Non-Inclusion). If a cluster $C$ labelled with $b_0 \ldots b_{d-1}$ exists then no cluster $C'$ with $C' \neq C$ whose label is prefixed with $b_0 \ldots b_{d-1}$ exists.

The length of a cluster label, i.e. the number of bits of that label, is called the dimension of the cluster. In the following, notation $d$-cluster denotes a cluster of dimension $d$. Dimension determines an upper bound on the number of links a cluster has with other clusters of the overlay, i.e. the number of its neighbours. Peers of a $d$-cluster $C$ maintain a routing table $RT$ such that entry $RT[i]$, with $0 \leq i < d$, points to peers belonging to one of the $d$ closest clusters.

\[ \text{Henceforth, a cluster will refer to both the cluster and its label.} \]
to $C$. (Distance notion is detailed in Section 4.2.2.) References to clusters that point toward $C$ are maintained by $C$’s members in a predecessor table $PT$. Note that maintaining such a data structure is not mandatory, i.e., those clusters can be easily found by the topological properties of PeerCube. However, keeping this information makes the maintenance operations more efficient. Regarding data, all the peers of a cluster are responsible for the same data keys and their associated data. As for most existing overlays, a data key is placed on the closest cluster to this key. Placing a data key on all the peers of a cluster naturally improves fault tolerance since this increases the probability that this key remains available even if some of the peers fail. To keep this probability high, the size of a cluster must not undershoot a certain predefined value $S_{min}$, which depends on the probability of peers’ failures. Finally, for scalability reasons, each cluster size is upper bounded by a constant value $S_{max}$ specified later on.

### 4.2.2 Hypercubic Topology

Clusters self-organise into a hypercubic topology, such that the position of a cluster into the hypercube is determined by its label. Ideally the dimension of each cluster $C$ should be equal to some value $d$ to conform to a perfect $d$-hypercube. However, due to churn and random identifier assignment, dimensions may differ from one cluster to another. Indeed, as peers may join and leave the system asynchronously, cluster $C$ may grow or shrink more rapidly than others. In the meantime, bounds on the size of clusters require that, whenever the size of $C$ exceeds $S_{max}$, $C$ splits into clusters of higher dimensions, and that, whenever the size of $C$ falls under $S_{min}$, $C$ merges with other clusters into a single new cluster of lower dimension. Finally, since peers IDs, and thus cluster labels, are randomly assigned, some of the labels may initially not be represented at all. For all these reasons dimensions of clusters may not be homogeneous. To keep the structure as close as possible to a perfect hypercube and thus to benefit from its topological properties, we need a distance function $D$ that allows to uniquely characterise the closest cluster of a given label. This is obtained by computing the numerical value of the “exclusive or” (XOR) of cluster labels $i\mathcal{E}$. To prevent two labels to be at the same distance from a given bit string, labels are suffixed with as many bits “0” as needed to equalise their size to $m$.

**Definition 1** (Distance $D$). Let $C = a_0 \ldots a_{d-1}$ and $C' = b_0 \ldots b_{d-1}$ be any two $d$ (resp. $d'$) -clusters:

$$D(C, C') = D(a_0 \ldots a_{d-1} 0^{m-d}, b_0 \ldots b_{d-1} 0^{m-d}) = \sum_{i=0}^{m-1} a_i \neq b_i 2^{m-i}$$

Distance $D$ is such that for any point $p$ and distance $\Delta$ there is exactly one point $q$ such that $D(p, q) = \Delta$ (which does not hold for the Hamming distance). Finally, labels that have longer prefix in common are closer to each other. We are now ready to detail the content of a cluster’s routing table. Let $C = b_0 \ldots b_{d-1}$ and $C' = b_0 \ldots \bar{b}_1 \ldots b_{d-1}$. Then, $C$’s $i$th neighbour in PeerCube is cluster $C'$ whose label is the closest to $C'$. \hspace{1cm} \text{Property 4.} Let $C$ be a $d$-cluster. Then, \forall $i, 0 \leq i < d$, entry $i$ of the routing table of $C$ is cluster $C'$ such that for each cluster $C'' \neq C'$, $D(C', C') < D(C', C'')$ holds.

By the distance $D$ definition, it is easy to see that if for each cluster $C$ in PeerCube the distance between $C'$ and its $i$th neighbour is equal to 0 (with $0 \leq i < d$), then PeerCube maps a perfect $d$-hypercube. From Property 4, we have:

**Lemma 1.** Let $C = b_0 \ldots b_{d-1}$ be a $d$-cluster. Then \forall $i, 0 \leq i < d$, $C$’s $i$th neighbour is cluster $C'$ such that $C'$ is prefixed with $b_0 \ldots \bar{b}_i$ if such a cluster exists. Otherwise, $C' = C$.

This can be seen by observing that, by definition of $D$, $C'$ shares the longest prefix with $C'$, that is at least the prefix $b_0 \ldots \bar{b}_i$. Otherwise $C'$ would be the closest cluster to $C'$. We exploit this property to construct a simple lookup protocol which basically consists in correcting the bits of the source towards the destination from the left to the right.

### 4.3 Leveraging the Power of Clustering

#### Dimensions Disparity

As described before, clusters dimensions are not necessarily equal to each other. By simply setting $S_{max} > \log_2 N$, we can make the dimensions disparity small and constant. Indeed, observe that the dimension of a cluster is necessarily greater than or equal to $\log_2 S_{max}$. This follows from the fact that the minimum number of clusters is $N/S_{max}$, which determines the minimum number of bits needed to code the label of a cluster. Furthermore, by setting $S_{max} > \log_2 N$, we can show by using Chernoff’s bounds that the dimension of a cluster is w.h.p.\hspace{1cm}\text{lower than } \log_2 \frac{N}{S_{max}} + 3. \text{ Indeed, since labels are uniformly randomly assigned, setting } S_{max} \text{ to a higher value decreases clusters dimension. Thus distance } \delta \text{ between any two clusters dimensions is w.h.p. less than or equal to } 3\hspace{1cm}\text{\textbullet}\text{Furthermore the number of non-represented prefixes is at most } 2^\delta, \text{ which is very small with regard to the total number of clusters } N/S_{max}. \text{ Consequently, by setting } S_{max} > \log_2 N, \text{ PeerCube is very close to a } (\log_2 \frac{N}{S_{max}})\text{-hypercube, which guarantees PeerCube to enjoy the attractive topological properties of a perfect hypercube of diameter } \log_2 \frac{N}{S_{max}}. \text{ Henceforth } S_{max} \text{ is in } \Theta(\log N)$.\hspace{1cm}\text{In the following, with high probability (w.h.p.) means with probability greater than } 1 - \frac{1}{N}.\hspace{1cm}\text{Note that for a pure hypercube, the dimension disparity is } \log_2 N.$
Limiting the Impact of Churn. We have just shown that by having peers self-organised in a hypercube of clusters we get w.h.p. an overlay of diameter \( \log_2 \frac{N}{S_{\text{min}}} \). We now describe how peers take advantage of that clustering to limit the impact of churn on the overall system. Specifically, peers within a cluster are classified into two categories: core and spare members. Only core members are in charge of PeerCube operations (i.e. inter clusters message forwarding, routing table maintenance, computation of cluster view membership, and keys caching). Size of the core set is equal to the minimal size of a cluster, i.e. constant \( S_{\text{min}} \). Core members form a clique, i.e., they point to each other. View of the core set is denoted \( V_c \). In contrast to core members, spare members are temporarily inactive, in the sense that they are not involved in any of the overlay operations. They only maintain links to a subset of core members of their cluster and cache the set of keys and associated data as core members do. Within a cluster, apart from the core members that maintain the view \( V_c \) of the spares set, no other peer in the system is aware of the presence of a particular spare, not even the other spares of the cluster. As a consequence, routing tables only point to core members, that is \( S_{\text{min}} \) references per entry are needed.

Achieving High Consistency. By keeping the size of the core set to a small and constant value, we can afford to rely on the powerful consensus building block to guarantee consistent routing tables among correct core members despite the presence of a fraction \( \mu \) of Byzantine peers among them. Briefly, in the consensus problem, each process proposes a value, and all the non-faulty processes have to eventually decide (termination property) on the same output value (agreement property), this value having been proposed by at least one process (validity property). Various Byzantine consensus algorithms have been proposed in the literature (good surveys can be found in \[8, 4\]). In PeerCube, we use the solution proposed by Kotla et al. \[11\] essentially because it provides optimal resiliency, i.e. tolerates up to \( \frac{n-1}{3} \) Byzantine processes in a group of \( n \) processes, and guarantees that a value proposed only by Byzantine processes is never decided by correct ones. Moreover, message complexity is in \( \mathcal{O}(n^3) \) in the worst case, and \( \mathcal{O}(n) \) in executions where Byzantine processes are not present. Note that in our context, \( n = S_{\text{min}} \).

4.4 PeerCube Operations

From the application point of view, three key operations are provided by the system: the \( \text{lookup}(k) \) operation which enables to search for key \( k \), the \( \text{join} \) operation that enables a peer to join the system, and the \( \text{leave} \) operation, indicating that some peer left the system. Note that the \( \text{put}(x) \) operation, that enables to insert data \( x \) in the system, is not described since it is very similar to the \( \text{lookup}(k) \) operation. From the topology structure point of view, three events may result in a topology modification: when the size of a cluster exceeds \( S_{\text{max}} \), this cluster \( \text{split} \) into two new clusters; when the size of a cluster goes below \( S_{\text{min}} \), this cluster \( \text{merge} \) with other clusters to guarantee the cluster resiliency; finally, when a peer cannot join any existing cluster because none of them matches the peer identifier prefix, then a new cluster is \( \text{create} \). For robustness reasons, a cluster may have to temporarily exceed its maximal size \( S_{\text{max}} \) before being able to split into two new clusters. This guarantees that resiliency of both new clusters is met, i.e both clusters sizes are at least equal to \( S_{\text{min}} \). A similar argument applies to the \( \text{create} \) operation. For this specific operation, peers whose identifiers do not match any cluster label, temporarily join the closest cluster to their identifier, and whenever \( S_{\text{split}} \geq S_{\text{min}} \) temporary peers share the same prefix then they create their new cluster. Threshold \( S_{\text{split}} \) is discussed in Section 4.4.2. These three additional operations exploit the recursive construction property of hypercubes to minimise topology changes, and rely on the Byzantine-consensus building block to achieve high consistency among routing tables. For space reasons, description of these operations are not presented in the paper. However, each of them is detailed in the companion paper \[1\].

4.4.1 \( \text{lookup} \) Operation

In this section we describe how peer \( p \in \mathcal{C} \) locates a given key \( k \) through the \( \text{lookup} \) operation. Basically, locating \( k \) consists in walking in the overlay by correcting one by one and from left to right the bits of \( p \)'s identifier to match \( k \). By Lemma \[1\] and by distance \( D \) this simply consists in recursively contacting the closest cluster to \( k \). In a failure-free environment, this operation would be similar to a typical lookup operation, except that if the originator \( p \) of the \( \text{lookup} \) was a spare member, then \( p \) would forward its request to a randomly chosen core member of \( \mathcal{C} \). Then the request would be propagated until finding either a peer of a cluster labeled with a prefix of \( k \), or no cluster closer to \( k \) than the current one. The last contacted peer would return to the originating peer \( p \) either the requested data if it exists, or null otherwise. Now, suppose that malicious peers may drop or misroute requests they receive to prevent them from reaching their legitimate destination. We adapt the \( \text{lookup} \) operation by using the \textit{width path} approach, commonly used in fault tolerant algorithms, which consists in forwarding a request to sufficiently enough peers so that at least one correct peer receives it. This is described in Figure \[1\]. Specifically, a request is forwarded to \( \lfloor (S_{\text{min}} - 1)/3 \rfloor + 1 \) randomly chosen core members of the closest cluster to the request destination, instead of only one randomly chosen core member as in the basic \( \text{lookup} \) op-
Upon lookup(k) from the application do
if (p.type ≠ core) then
   \{q₀ \ldots q_{\lfloor(S_{\text{min}}-1)/3}\} ← p.coreRandomPeer();
p sends (LOOKUP, k,p) to \{q₀ \ldots q_{\lfloor(S_{\text{min}}-1)/3}\}
else
   \hat{C} ← \text{findClosestCluster}(k);
p sends (LOOKUP,k,p) to \{q₀ \ldots q_{\lfloor(S_{\text{min}}-1)/3}\}
enddo
Upon receiving (LOOKUP,k,q) from the network do
\hat{C} ← \text{findClosestCluster}(k);
if (p.cluster.label=\hat{C}) then
   \text{p sends (LOOKUP, k,q) to core members in \hat{C} if not already done;}
data ← k’s data if cached otherwise null;
sends (k,\hat{C}.data) to the originating q by using the reverse path;
else
   \text{p sends (LOOKUP, k,q) to a random subset of}\n   \{(S_{\text{min}}-1)/3\} + 1 peers in C.coreSet;
enddo
\text{findClosestCluster}(k)
if (p.dim=0 or p.cluster.prefix(k)) then
   \hat{C} ← p.cluster;
else
   C.label ← RT_p(0).label;
   for (i = 0 to p.dim − 1) do
      if (D(k,RT_p(i).label) < D(k,C.label)) then
         C.label ← RT_p(i).label;
   return C;

Figure 1. lookup Operation at Peer p

Upon join(p) from the application do
\{q₀ \ldots q_{\lfloor(S_{\text{min}}-1)/3}\} ← \text{findBootstrap}();
p sends (JOIN,p) to q ∈ \{q₀ \ldots q_{\lfloor(S_{\text{min}}-1)/3}\};
enddo;
Upon receiving (JOIN,q) from the network do
\hat{C} ← \text{findClosestCluster}(q.id);
if (p.cluster=\hat{C}) then
   \text{if (p.cluster.prefix(q.id)) then}
      \text{p broadcasts (JOINSPARE,C,q) to p’s core set;}
   else
      \text{p broadcasts (JOINTEMP,C,q) to p’s core set;}
   else
      \text{p sends (JOIN,q) to a random subset of}\n      \{(S_{\text{min}}-1)/3\} + 1 peers in C’s core set;
enddo;
Upon delivering (JOINSPARE,C,q) from the network do,
   V_{\text{q}} ← V_{\text{q}} \cup q;
   if (p.clusterIsSplit) then p.split();
   N ← p.findClosestCluster(q.id);
p sends (JOINACK, N.state) to q;
enddo;
Upon delivering (JOINTEMP,C,q) from the network do;
   p.temp ← p.temp \cup q;
   if (p.tempIsSplit) then p.create(p.temp);
   C ← p.findClosestCluster(q.id);
p sends (JOINACK, N.state) to q;
enddo;

Figure 2. join Operation at Peer p

operation. In addition, in the last contacted cluster \( C \), when
a core member \( p \in C \) receives the request, if \( p \) has not al-
ready sent it to all core members of \( C \) then it does so and
returns the response through the reverse path. Hence, each
peer that forwarded the request waits for a quorum of re-
spawns (i.e., \[(S_{\text{min}}-1)/3\] + 1) before propagating the
response back in the reverse path. When the originator \( q \)
of the lookup request receives \[(S_{\text{min}}-1)/3\] + 1 similar
responses \((k,\text{data},C)\) issued from peers whose ID prefix
matches the one \( q \) initially contacted, then \( q \) can safely use
the received data. Otherwise, \( q \) discards it. It is easy to
see that if there are no more than \[(S_{\text{min}}-1)/3\] malicious
core members per cluster crossed, then a lookup operation
invoked by a correct peer returns the legitimate response.

Lemma 2. The lookup(k) operation returns the data as-
associated to \( k \) if it exists, null otherwise. This is achieved in
\( O(\log N) \) hops and requires \( O(\log N) \) messages.

For space limitations, proofs of lemmata are omitted
from the paper. However, they are available in [1].

4.4.2 join Operation

Recall that by construction each cluster \( C \) contains all the
core and spare members \( p \) such that \( C \)’s label is a prefix of
\( p \)’s ID, and that each peer \( p \) belongs to a unique cluster. To
join the system, peer \( p \) sends a join request to a correct peer
it knows in the system. The request is forwarded until
finding the closest cluster \( C \) to \( p \)’s ID. Two cases are possi-
able: either \( C \)’s label matches the prefix of \( p \)’s ID or the
cluster \( N \) \( p \) should be inserted into does not already exist
\( (C \) is only the closest cluster to \( N \) \). In the former case, \( p \)
is inserted into \( C \) as a spare member. Inserting newcomers
as spare members prevent malicious peers from designing
deterministic strategies to increase their probability to act as core member. In the latter case, \( p \) is temporarily in-
serted into \( C \) until creation of \( N \) is possible, i.e., predicate
tempIsSplit() in Figure2 holds. This predicate holds if there exist \( S_{\text{split}} \) temporary peers in \( C \) that share a com-
mon prefix. Note that temporary peers do not participate in
the cluster life (they do not even cache data, contrary
to spares), and only core members are aware of their pres-
ence. Threshold \( S_{\text{split}} \) is introduced to prevent the adver-
sary from triggering a “split-merge” cyclic phenomenon.
Indeed, a strong adversary can inspect the system and lo-
cate the clusters that are small enough so that the departure
of malicious peers from that cluster triggers a merge op-
eration with other clusters, and their re-joining activates a
split operation of the newly created cluster. Thus by setting
\( S_{\text{split}} = S_{\text{min}} > \lceil \frac{S_{\text{max}}-1}{3} \rceil \) the expected number of malicious peers in a cluster, probability of this
phenomenon is negligible. In both cases, i.e. whether \( p \)
is inserted as spare or temporary peer of \( C \), \( p \)’s insertion
is broadcast to all core members. The broadcast primitive guarantees that if a correct sender broadcasts some message $m$, then all correct recipients eventually deliver $m$ once. Peer $p$’s insertion in a cluster is acknowledged to $p$ by all correct core members of $p$’s new cluster via a JOIN message which carries information (state) that $p$ needs to join its cluster (whether $p$ is spare or temporary, and the required data structures, if any). In all cases, a constant number of messages are needed. Thus message complexity of a join is $O(\log N)$ which is the cost of the lookup for $C$.

**Lemma 3.** The join operation is insensitive to collusion. That is if before a join operation in $C$ the expected number of malicious peers in $C$ is $\mu S_{\min}$, then after a join in $C$ the expected number of malicious peers is still equal $\mu S_{\min}$.

### 4.4.3 Leave Operation

The leave operation is executed when a peer $q$ wishes to leave a cluster or when $q$’s failure has been detected. Note that in both cases, $q$’s departure has to be detected by $\lceil (2S_{\min} + 1)/3 \rceil + 1$ core members so that a malicious peer cannot abusively pretend that some peer $q$ left the system. Thus, when core members detect that $q$ left, two scenarios are possible. Either $q$ belonged to the spare set, in which case, core members simply update their spare view to reflect $q$’s departure, or $q$ belonged to the core set. In the latter case, $q$’s departure has to be immediately followed by the core view maintenance to ensure its resiliency (and thus the cluster resiliency). To prevent the adversary from devising collusive scenario to pollute the core set, the whole composition of the core set has to be refreshed. Indeed, replacing the peer that left by a single one (even randomly chosen within the spare set) does not prevent the adversary from ineluctably corrupting the core set: once malicious peers succeed in joining the core set, they maximise the benefit of their insertion by staying in place; this way, core sets are eventually populated by more than $\lceil S_{\min} + 1 \rceil$ malicious peers, and thus become – and remain – corrupted. This is illustrated in Section 5. Thus each core member chooses $S_{\min}$, random peers among both core and spare members, and proposes this subset to the consensus. By the consensus properties, a single decision is delivered to all core members, and this decision has been proposed by at least one correct core member. Thus core members agree on a unique subset which becomes the new core set. Note that in addition to preventing collusion, refreshing the whole core set guarantees that the expected number of malicious peers in core sets, and thus the number of corrupted entries in routing tables is bounded by $\mu S_{\min}$ which is minimal:

**Lemma 4.** After a core member’s departure, the expected number of malicious peers in that core is at most $\mu S_{\min}$.

**Lemma 5.** Upon a core member’s departure, for any randomized algorithm, there exists an adversarial strategy such that the expected number of malicious peers in the core is at most $\mu S_{\min}$.

Remark that because of the asynchrony of the system, some of the agreed peers $s_i$ may still belong to some views while having been detected as failed or left by others, or may belong to only some views because of their recent join. In the former case, all the correct core members eventually deliver the consensus decision notifying $s_i$’s departure, and new consensus is run to replace it. Note that for efficiency reason, each core member can ping the peers it proposes before invoking the consensus. In the latter case, $s_i$’s recent arrival is eventually notified at all correct core members by properties of the broadcast primitive (see join operation), and thus they insert $s_i$ in $V_s$. Then each core member $p$ notifies all the clusters that point to $C$ (i.e. entries of $p$’s PT table) of $C$’s new core set. Core members of each such cluster can safely update their entries upon receipt of $\lceil S_{\min} + 1 \rceil + 1$ similar notifications. This is encapsulated into the leavePredicate() procedure in Figure 3. Similarly, all the peers $\{s_1, \ldots, s_{\min}\}$ are safely notified about their new state, and locally handle the received data structures (invocation of leaveRoutingTable() procedure). Former core members only keep their keys and the associated data. In all cases a constant number of messages are exchanged for a leave.

## 5 Handling Collusion

### 5.1 Thwarting Eclipse Attacks

An eclipse attack enables the adversary to control part of the overlay traffic by coordinating its attack to infiltrate routing tables of correct peers. As shown in the previous section, PeerCube operations thwart those attacks es-
sentially by preventing colluders from devising deterministic strategies to join core sets (i.e., newcomers are inserted as spare members) and by reaching agreement among core members on any event that affects PeerCube topology. Correctness of these operations relies on the hypothesis that no more than \( \lceil S_{\text{max}} \rceil \) malicious peers populate core sets, that is the fraction of malicious peers in any core set is no more than \( 1/4 \). Probability that such an assumption does not hold is now discussed. Let us first compute the upper bound on the probability to corrupt a core set. This holds when the clusters number is minimal (i.e. equal to \( \lfloor S_{\text{max}} \rfloor \)). Denote by \( X_u \) the random variable describing the number of malicious peers in a cluster, and by \( Y_u \) the random variable describing the number of malicious peers in a core. Clearly, \( Y_u \) depends on \( X_u \). Since identifiers are randomly chosen, inserting malicious peers into clusters can be interpreted as throwing \( \mu N \) balls one by one and randomly into \( \frac{N}{S_{\text{max}}} \) bins. The probability that \( x \) balls (malicious peers) are inserted into a bin (cluster) is \( P(X_u = x) = (\frac{\mu N}{x})(\frac{S_{\text{max}}-x}{S_{\text{max}}})^x (1 - \frac{S_{\text{max}}}{N})^{\mu N - x} \). By the leave operation, each departure from a core set is followed by the rebuilding of this set with \( S_{\text{min}} \) randomly chosen peers among the \( S_{\text{max}} \) peers of the cluster. This can be interpreted as picking simultaneously \( S_{\text{min}} \) balls among \( S_{\text{max}} \) balls among which \( x \) are black (malicious peers) and \( S_{\text{max}} - x \) are white (correct ones). Thus, the probability of having \( y \) malicious peers inserted in the core, knowing the number of malicious peers \( x \) in the cluster, is given by

\[
P(Y_u = y | X_u = x) = \binom{S_{\text{max}}}{y} \left(\frac{S_{\text{max}}-y}{S_{\text{max}}}\right)^y \left(1 - \frac{S_{\text{max}}}{N}\right)^{\mu N - x}.
\]

Finally, the tight upper bound on the corruption probability is equal to \( p_u = 1 - \sum_{y=0}^{\lceil S_{\text{max}} \rceil}{\binom{S_{\text{max}}}{y} (\frac{S_{\text{max}}-y}{S_{\text{max}}})^{y} (1 - \frac{S_{\text{max}}}{N})^{\mu N - x}} \). By proceeding as above, the tight upper bound on the corruption probability is \( p_l = 1 - \sum_{l=0}^{\lfloor S_{\text{max}} \rfloor}{\binom{S_{\text{max}}}{l} (\frac{S_{\text{max}}-l}{S_{\text{max}}})^{l} (1 - \frac{S_{\text{max}}}{N})^{\mu N - x}} \).

We can now derive upper and lower bounds on the probability that a request reaches its legitimate destination. The probability that the number of hops of a request be \( h \) is equal to \( \left(\frac{d_{\text{max}}}{h}\right) \binom{d_{\text{max}}}{\frac{h}{2}} \), with \( d_{\text{max}} = \log_2 \left( \frac{N}{S_{\text{max}}} \right) + 3 \) the maximal dimension of a cluster. Such a request is successful if none of the \( h \) clusters crossed by this request are corrupted. Thus its probability of success is at least \( \sum_{h=\lfloor d_{\text{min}} \rfloor}^{d_{\text{max}}}{\binom{d_{\text{max}}}{h} \left(2^{-h} \left(1-p_u\right)^{h}\right)} \), and at most \( \sum_{h=0}^{\lfloor d_{\text{min}} \rfloor}{\binom{d_{\text{min}}}{h} \left(2^{-h} \left(1-p_l\right)^{h}\right)} \), with \( d_{\text{min}} = \log_2 \left( \frac{N}{S_{\text{max}}} \right) \).

Recall that the policy we propose to replace a left core member is to refresh the whole composition of the core set by randomly choosing peers within the cluster. We opposed this policy to the one which consists in replacing the core member that left by a single one randomly chosen in the cluster (see Section 4.4.3). Figure 4 compares the lower bound on the probability of successful requests with these two policies according to \( S_{\text{max}} \), for different ratio of malicious peers in the system, and considering \( N = 1, 000 \). The first observation is that probability of success for the policy we propose (labelled by \textit{with randomisation in the Figure}) varies lightly with \( S_{\text{max}} \) value. This confirms that setting \( S_{\text{max}} > O(\log N) \) does not bring any additional robustness to PeerCube. The second observation is that for the second policy (denoted by \textit{w/o randomisation}), that probability drastically decreases with increasing values of \( S_{\text{max}} \), even for small values of \( \mu \). This corroborates the weakness of such a policy in presence of a strong adversary.

![Figure 4. Probability of success of requests w.r.t. \( S_{\text{max}} \)](image-url)
procedure by invoking the lookup operation on keys obtained by successively correcting bits \( p_i, p_{i+1}, \ldots, p (i+b-1) \mod b \) for \( 0 \leq i \leq b-1 \). Other independent routes of non-optimal length are found by modifying first, one bit on which \( p \) and \( q \) both agree (say \( n_i \)), by looking for the closest cluster to that key, then by finding independent routes from that cluster by proceeding as above, and finally by re-modifying \( n_i \).

**Lemma 6.** The independent routes algorithm finds at least \( \log_2 \frac{N}{S_{max}} \) independent routes of length \( O(\log N) \) w.h.p.

We now examine the probability \( p_{\text{succ}} \) for a request issued by a correct peer to reach its legitimate destination when that request is sent over \( r \) independent routes of length \( h \), with \( \Sigma_{h=0}^{d_{\text{min}}} \leq r \leq d_{\text{max}} \). The request is successful if at least one route does not contain any corrupted cluster. Let \( p_{t} \) denote the exact probability that a cluster is corrupted, i.e. \( p_{t} \leq p \leq p_{u} \). The probability of success of a request using \( r \) independent routes of length \( h \) is

\[
1 - \left(1 - (1 - p)^h \right)^r.
\]

Thus probability \( p_{\text{succ}} \) is lower bounded by

\[
\Sigma_{h=0}^{d_{\text{max}}+2} \left( \frac{d_{\text{max}}+2}{h} \right) \left( \frac{1}{2} \right)^{d_{\text{max}}+2} \left( 1 - (1 - p_{u})^h \right)^r
\]

and upper bounded by

\[
\Sigma_{h=0}^{d_{\text{min}}} \left( \frac{d_{\text{min}}}{h} \right) \left( \frac{1}{2} \right)^{d_{\text{min}}} \left( 1 - (1 - p_{t})^h \right)^r.
\]

Term \( d_{\text{max}} + 2 \) in the first equation comes from the non-optimal paths of the independent routing algorithm. Figure 5 shows the remarkable increase in PeerCube robustness when using independent routes w.r.t. to a single route. Note also that whatever the percentage of malicious peers in the system the probability of success degrades gracefully (logarithmically) with respect to \( N \).

### 6 Simulation

In this section, we present the results of an experimental evaluation of PeerCube performed on PeerSim a simulation platform for P2P protocols. The simulation is event based. The workload is characterised by the number of and arrival/departure pattern of peers and by the distribution of requests they issue. Each experiment uses a different workload.

**Churn Impact** In these experiments, we study the ability of PeerCube to greatly reduce the impact of high dynamics on peers load. In particular, we analyse the benefit drawn from appointing newcomers as spare members on the number of routing tables updates. In Figure 6 the number of routing tables updates in a network of up to 10,000 peers is depicted. Bursts of joins and leave are cyclically generated (every 500 simulation time unit, up to 500 peers issue join or leave operations). \( S_{max} = 13 \), and \( S_{min} = 4 \). A failure-free environment is assumed. The dotted curve shows the number of triggered routing tables updates in a cluster-based hypercubic topology in which all clusters members actively participate in the overlay operations (denoted by PeerCube without core/spare classification in the figure), while the solid curve depicts the number of routing tables updates generated in PeerCube (denoted by PeerCube). As expected, using newcomers as hot spares drastically reduces the number of routing tables updates for both joins and departures events. For instance, the burst of joins generated during simulation time 27,000 and 27500 have triggered no routing tables updates for PeerCube while it has given rise to 50,400 updates for PeerCube without core/spare classification.

**Robustness against Collusion** In these experiments, we test the ability of PeerCube to achieve a robust lookup operation despite the presence of a strong adversary. As described in the previous section, robust lookup is realized by two techniques. First, by preventing malicious peers from strategizing to get inserted within core sets; through the randomization insertion algorithm, we minimize the ratio of
malicious peers into routing tables. Second, by taking advantage of independent and optimal length paths offered by the hypercubic topology to guarantee that a request sent by a correct peer reaches its legitimate destination with probability close to 1. Figure 7 shows for N = 1,000 peers, the probability of successful requests sent by correct peers w.r.t. to the ratio of malicious peers in the system. The main observation is that experiments fully validate theoretical results. Namely, for up to 15% of malicious peers, 98% of the requests issued from correct peers are successful, and for 25% of malicious peers, in average, 90% of the requests are successful, which clearly emphasises PeerCube robustness to co-ordinated malicious behaviour.

7 Conclusion

In this paper we have presented PeerCube, a DHT-based system that is able to handle high churn and collusive behavior. Many existing P2P systems exhibit some fault tolerance or churn resiliency. The main contribution of PeerCube is to combine existing techniques from classical distributed computing and open large distributed systems in a new way to efficiently decrease churn impact and to tolerate collusion of malicious peers as shown analytically and validated through experimental simulation. For future work, we are planning to study strategies against a computationally unbounded adversary, that is an adversary, beyond being able to inspect the whole system and issue join and leave requests as often it wishes (as studied in this paper), can carefully choose the IDs of the Byzantine peers, so that it can place them at critical locations in the network [7, 21].

Acknowledgment

We would like to thank the CAPES-COFECUB program 497-05 for having partially supported this work.
