HIGHLIGHTS
► Study of Hg concentration in four cores from Belgian peat bog.
► Reconstruction of Hg deposition over last 1500 years.
► Maximum Hg accumulation rates ranging from 90 to 200 μg m⁻² y⁻¹ are recorded between 1930 and 1980 AD.
► The average Hg accumulation rate before the influence of human activities (e.g. 1300 AD) was 1.8 ± 1 μg m⁻² y⁻¹.
► The predominant anthropogenic Hg sources were coal burning and smelter Hg emissions.

ABSTRACT

Four sediment cores were collected in 2008 from the Misten ombrotrophic peat bog in the Northern part of the Hautes Fagnes Plateau in Belgium. Total mercury (Hg) concentrations were analyzed to investigate the intra-site variability in atmospheric Hg deposition over the past 1500 years. Mercury concentrations in the four cores ranged from 16 to 1100 μg kg⁻¹, with the maxima between 840 and 1100 μg kg⁻¹. A chronological framework was established using radiometric ²¹⁰Pb and ¹⁴C dating of two cores (M1 and M4). Pollen horizons from these two cores were correlated with data from two additional cores, providing a consistent dating framework between all the sites. There was good agreement between atmospheric Hg accumulation rates in the four cores over time based on precise age dating and pollen chronosequences. The average Hg accumulation rate before the influence of human activities (from 500 to 1300 AD) was 1.8 ± 1 μg m⁻² y⁻¹ (2SD). Maximum Hg accumulation rates ranged from 90 to 200 μg m⁻² y⁻¹ between 1930 and 1980 AD. During the European–North American Industrial Revolution, the mean Hg accumulation rate exceeded the pre-Industrial values by a factor of 63. Based on comparisons with historical records of anthropogenic activities in Europe and Belgium, the predominant regional anthropogenic sources of Hg during and after the Industrial Revolution were coal burning and smelter Hg emissions. Mercury accumulation rates and chronologies in the Misten cores were consistent with those reported for other European peat records.

1. Introduction

Mercury (Hg) has been used for thousands of years and more recently it has been used in a large number of industrial processes (Pacyna et al., 2006). Mercury is a metal that is toxic to humans and wildlife at low concentrations (Morel et al., 1998; Mergler et al., 2007). Natural Hg sources include volcanic activity, erosion and marine emissions (Schroeder and Munthe, 1998). The principal anthropogenic Hg emission sources are coal fired power plants, chlorine production, non-ferrous metallurgy, cement production, and primary and secondary lead and zinc production (Wilson et al., 2006; Pacyna et al., 2006; Pirrone and Mason, 2009). More than 95% of natural and anthropogenic Hg emissions are mainly in elementary form (Hg⁰) with a residence time of 6–12 months in the atmosphere (Schroeder and Munthe, 1998; Fitzgerald and Lamborg, 2007; Pirrone and Mason, 2009). Long-range transport of Hg emissions has resulted in the contamination of remote ecosystems, generating a serious environmental problem that transcends national boundaries (Pirrone and Keating, 2010). Hylander and Melili (2003)
suggested that the current rate of global Hg emission (until 2000) to the atmosphere was approximately 3 times higher than during the pre-Industrial Revolution. The Industrial Revolution was a period from 1750 to 1850 marked by an increase in industrial activities, coal burning, and petroleum use. Similarly, Lindberg et al. (2007) estimated that atmospheric Hg deposition to remote ecosystems globally had increased by a factor of 3 since the start of the Industrial Revolution (1700 AD). To determine the regional versus global contributions, it is important to quantify the origin of this atmospheric Hg and its spatio-temporal variations.

Several types of environmental archives (lake and marine sediments, ice and peat) have been used to provide information about Hg deposition during the last thousand years (e.g., Gobell et al., 1999; Bindler et al., 2001; Biester et al., 2002; Roos-Barraloucgh et al., 2002; Givelet et al., 2004a, 2004b). Peat records from ombrotrophic peatlands that receive inputs by way of the atmosphere are unique archives of anthropogenic and natural deposition of trace elements (e.g., Shotyk et al., 1996, 2001; Martinez Cortizas et al., 1997, Farmer et al., 2009; Zaccone et al., 2009; Manneville et al., 2006).

Data from ombrotrophic peat bogs, (Martinez Cortizas et al., 1999; Roos-Barraloucgh et al., 2002; Biester et al., 2002; Shotyk et al., 2003) have been utilized to reconstruct the evolution of atmospheric Hg deposition over long-term periods (e.g., the Holocene). In these studies, the Hg accumulation rate was calculated by combining the accumulation rate and density of the peat bog and Hg concentration (Madson, 1981; Jensen and Jensen, 1990; Norton et al., 1997; Martinez Cortizas et al., 1999; Roos-Barraloucgh et al., 2002; Givelet et al., 2004a, 2004b), and Hg was assumed to be immobile and well preserved in ombrotrophic peat (e.g. Benoît et al., 1998; Roos-Barraloucgh et al., 2002; Givelet et al., 2004a, 2004b; Shotyk et al., 2003, 2005). However, most authors (e.g. Rydberg et al., 2010; Biester et al., 2003) have suggested that Hg concentrations in peat bogs could be affected by natural biogeochemical processes such as peat decomposition and early diagenesis. This hypothesis was tested, but not validated, by Otrtridge et al. (2011) using an age-dated permafrost peat core from Northern Canada. Thus to use Hg concentrations in peat bogs as a record over time requires a pre-age-dated permafrost peat core from Northern Canada. Thus to use such a core, we used the accumulation rate and density of the peat bog and Hg concentration (Madson, 1981; Jensen and Jensen, 1990; Norton et al., 1997; Martinez Cortizas et al., 1999; Roos-Barraloucgh et al., 2002; Givelet et al., 2004a, 2004b), and Hg was assumed to be immobile and well preserved in ombrotrophic peat (e.g. Benoît et al., 1998; Roos-Barraloucgh et al., 2002; Givelet et al., 2004a, 2004b; Shotyk et al., 2003, 2005). However, most authors (e.g. Rydberg et al., 2010; Biester et al., 2003) have suggested that Hg concentrations in peat bogs could be affected by natural biogeochemical processes such as peat decomposition and early diagenesis. This hypothesis was tested, but not validated, by Otrtridge et al. (2011) using an age-dated permafrost peat core from Northern Canada.

2. Materials and methods

2.1. Sampling site and sample collection

The Misten peat bog is located in Eastern Belgium, ~5 km from the German border (Fig. 1). The peat bog surface has higher relief than surrounding area. A titanium Wardena corer from the University of Heidelberg was used to recover the upper first meter. The length of all peat cores was between 90 and 110 cm. A Belarus corer was therefore used to core deeper (core name MIS-08-01b). Maximum peat thickness reaches up to 8 m (Wastiaux and Schumacker, 2003), dating back to 9000 years (De Vleeschouwer et al., 2007). Based on geochemical parameters (Ca/Mg ratio, Sr concentrations), the Misten peat bog described as ombrotrophic for the upper 6.5 m and minerotrophic between 6.5 and 8 m. Although, ombrotrophic peatlands receive inputs from the atmosphere, the minerotrophic component also receives water influenced by surrounding soils and rocks.

The four peat cores MIS-08-01W (M1), MIS-08-04W (M2), MIS-08-05W (M3) and MIS-08-06W (M4) were collected in February 2008 using a Wardena corer (Fig. 1) in the most protected part of the natural reserve “Les Hautes-Fagnes”. The distance between the four cores was 50 to 100 m. The length of all peat cores was between 90 and 110 cm. Following the protocol described by Givelet et al. (2004a, 2004b), the cores were frozen (~40 °C) and cut by a stainless steel band saw (thickness of each sample ~1.5 cm). The peat samples were freeze-dried (at ~40 °C, pressure ~10−1 mbar) during approximately 1 week and powdered using an agate ball mill.

2.2. Ash content and humification

The mineral matter content of the peat, defined as “ash content”, was determined for all samples in cores M1 and M4 and every other sample in cores M2 and M3. Peat samples were dried at 105 °C over night and subsequently weighed to obtain the dry weight. Between 0.1 and 1 g of dried peat was then placed in oven at 550 °C for 6 h, to remove all organic matter by combustion (Chambers et al., 2011).

The degree of humification was estimated by colorimetry on peat alkaline extracts (Chambers et al., 2011). Two hundred milligrams of dried peat were reduced to powder and placed in an Erlenmeyer flask. One hundred milliliters of NaOH (8%) were added and the solution was boiled for 1 h. After cooling, the solution was diluted to 200 ml with MQ distilled water, then homogenized and filtered using no.1 Whatman filter paper. Fifty milliliters were taken and diluted with an equal volume of distilled water, and then directly placed in a spectrophotometer at the Scientific Station of the “Hautes Fagnes” (SSHF, University of Liege), for absorbance measurement at 540 nm. For every 10 samples, a standard with a humification level of 100% (Humic acid technical, ALDRICH) was included in the measurement. The ratio between the absorption values in the peat samples and peat standard was transformed to humification percentage.

2.3. Hg analysis

Mercury concentration was measured using a Milestone® DMA-80 at the Geosciences Environment Toulouse laboratory (France). All samples of the upper 25 cm of the cores and every other sample below this depth were measured. From 20 to 120 mg of dried bulk peat samples were used for analysis. Mercury concentrations were measured using an atomic absorption spectrophotometer after combustion and reduction of all forms of Hg to elemental Hg. Calibration was performed using ombrotrophic peat reference material (NIST/UEF/FM/001/NIST 1575) and peach leaves (NIST 1547). During each series of analyses, standards were analyzed three times before the first sample then between the samples. The average measured values were 162 ± 9μg kg−1 (n = 9) for NIMT.
(certified value 164 ± 20 μg kg⁻¹), 150 ± 30 μg kg⁻¹ (n = 5) for NIST 1575 (certified value 150 ± 50 μg kg⁻¹), and 38 ± 3 μg.kg⁻¹ (n = 3) for NIST 1547 (certified value 33 ± 5 μg kg⁻¹). All samples were analyzed in duplicate or triplicate.

2.4. Data analyses

Summary statistics were computed using Microsoft Office Excel 2010. The correlation coefficients (r) allow for the assessment of the degree of linear relationship between two variables. Relative standard deviation (% RSD) was calculated by dividing mean Hg accumulation rates (Hg AR) by standard deviation (SD), which is expressed as %. Bulk density (g cm⁻³) was estimated by dividing the dry weight (g) by fresh sample volume (cm³). Hg AR (μg m⁻² y⁻¹) were calculated as follows (Givelet et al., 2004a, 2004b):

\[
Hg\;AR = 10 \times [Hg] \times BD \times PAR\;(cm\;y^{-1})
\]

where [Hg] is the concentration (μg kg⁻¹), BD is the bulk density of the peat (g cm⁻³), and PAR is the peat accumulation rate (cm y⁻¹).

2.5. Elemental analysis

Fifty-five elements were measured in core M1 (unpublished data). Only lead (Pb), manganese (Mn), iron (Fe), calcium (Ca), magnesium (Mg), and titanium (Ti) are used in this study. Calcium and Mg are used to identify the peat status (ombrotrophic or minerotrophic peat, e.g. Shotyk et al., 1996). The concentrations of Ti is applied to quantify the natural “background” or lithogenic component of trace elements as brought by dust (Shotyk et al., 2001). Manganese and Fe are applied to understand the redox state of the samples (Steinmann and Shotyk, 1997). Lead is considered as immobile in the peat column and is largely enriched in the recent layers of European mires. It can be used as an indicator of the importance of the atmospheric input of anthropogenic trace metals.

Dry peat samples of ±100 mg were digested by microwave at the Institute of Earth Sciences (University of Heidelberg) using a mixture of HNO₃ (3 ml) and HBF₄ (0.1 ml). Organic matter was removed from the digested solution by addition of H₂O₂ (Krachler et al., 2002; Givelet et al., 2004a, 2004b). Element-concentrations were measured by inductively coupled plasma mass spectroscopy (Agilent quadrupole ICP-MS), at Geosciences Environment Toulouse laboratory (Toulouse, France). The plant standards (ICTJ CTA-OTL-1 Oriental Tobacco Leaves, NIST tomato leaves 1573 and IAEA lichen 336) were analyzed with each series of samples, in order to determine the precision and reproducibility of analytical procedures. Comparison between reference values and measured values are satisfactory within 88–97%.

2.6. Age dating

Radiocarbon age dating was done using stems, branches or leaves of plant material collected under a binocular microscope. Samples were prepared at the GADAM Center for Excellence (University of Gliwice, Poland) and measured by acceleration mass spectrometer (AMS) in Poznan, according the protocol described by Piotrowska et al. (2010, 2011). Activities of 210Pb were indirectly determined in cores M1 and M4 by the measurement of its decay product 210Po using a Canberra 740 alpha spectrometer (Sikorski and Bluszcz, 2008; De Vleeschouwer et al., 2010). The constant rate of supply (CRS) model (Appleby, 2008) was applied for the 210Pb dating. The maximum depth at which 210Pb could be detected was 22 cm for the core M1 (Table 1). Ten samples in the core M1 were dated by this method (Table 2). The M1 (200 cm) was cross referenced using the Wardenaar section and two Belorussian sections from the Misten peat bog previously dated. In this study we focus on the upper Wardenaar core (M1).

The composite age-depth for M1 was obtained by coupling the ¹⁴C and ²¹⁰Pb to generate an age interval for each sample (Piotrowska et al., 2010, 2011). The ²¹⁰Pb age was obtained by applying a Gaussian distribution of an age a function of depth, with a standard deviation of several years (Piotrowska et al., 2010). The total...
where $C_{\text{sup}}$ is the supported activity, constant and $C_{\text{tot}}(0)$ is the total $^{210}\text{Pb}$ activity of the sediment at the time of burial.

All $^{210}\text{Pb}$ and $^{14}\text{C}$ data were processed using the ‘Bacon’ software (Blaauw and Christen, 2011) to establish an age model and age range for each peat section (Fig. 2).

### 2.7. Pollen analysis

The obtained age-depth model for C1 and data from the a core previously described by De Vleeschouwer et al., 2012, were applied along with the pollen horizons to stratigraphically correlate the four cores. The pollen and spore composition for each of the four cores were analyzed at the Palaeobiogeology, Palaeobotany and Palaeopalynology laboratory (University of Liege, Belgium). About 2 g of fresh peat were treated with hydrochloric acid (HCL 10%), pure acetic acid and acetylis and the residues were washed by sieving through 200 µm and 12 µm meshes.

### 3. Results

#### 3.1. Density, ash content and humification

In core M1 peat accumulation rate increased slightly from 100 cm at base to 2 mm yr$^{-1}$ at 84 cm depth (447–692 AD) and then declined to 22 cm (1850–1864 AD) were it was lowest value (0.2 mm yr$^{-1}$). From this depth upward, the values increase again and reach a maximum of 15 mm yr$^{-1}$ at the peat surface (2008–2011 AD). The peat accumulation rates were calculated for cores M2 and M3, considering that the accumulation rate is constant in all pollen zones, by using the correlation between pollen record and the age dating of cores M1 and M4.

Peat density in the 4 cores varied from 0.01 g cm$^{-3}$ to 0.2 g cm$^{-3}$, reflecting the shift from the living plants of the bog acroton to the catotelm (Fig. 4). Thus density values increase from the lower part of the cores up to 15–25 cm, and then they decrease to the surface.

Ash contents of 0.3–10% are typical of ombrotrophic peats (Fig. 4). In the case of Misten bog, higher values around 10% can indicate additional input of inorganic particles by human activities: eroded soil particles of eroded soil particles but also industrial particles from coal burning and smelting. The degree of humification is very low (≤20%) in the upper 10–15 cm and generally increases with depth (Fig. 4).

### 3.2. Hg concentrations

Average Hg concentrations were similar in the lower part of the four cores (35 ± 15 μg kg$^{-1}$), and gradually decreased from ~30 to 40 cm to reach a maximum value between 13 and 27 cm (Fig. 4). The maximum Hg concentration recorded in core M1 was 840 μg kg$^{-1}$ (at 19 cm-depth), core M2 was 890 μg kg$^{-1}$ (at 27 cm-depth), core M3...
was 870 \( \mu g \cdot kg^{-1} \) (at 18 cm-depth), and in core M4 was 1130 \( \mu g \cdot kg^{-1} \) (at 12 cm-depth). For the core M1, the concentrations average 35±9 \( \mu g \cdot kg^{-1} \) from the base (91 cm) to 34 cm-depth. For the cores M2 and M3, Hg concentrations start to increase occurred at 35 and 25 cm deep, respectively. Below these depths the average concentrations is 46±13 \( \mu g \cdot kg^{-1} \) (35 to 108 cm), and 45±12 \( \mu g \cdot kg^{-1} \) (25 to 93 cm), respectively. For the core M4 the onset of the major Hg increase occurs at 29 cm-depth, below this depth average Hg concentration is 37±10 \( \mu g \cdot kg^{-1} \). In the upper most section of the four cores, Hg concentration decreased to values 45 \( \mu g \cdot kg^{-1} \) (0 cm-depth) for M1, 30 \( \mu g \cdot kg^{-1} \) (1.5 cm-depth) for M2, 29 \( \mu g \cdot kg^{-1} \) (1 cm-depth) for M3, and 70 \( \mu g \cdot kg^{-1} \) (1 cm-depth) for M4. Maximum humification values occurred in the lower sections, while the maximum Hg concentration was observed in the upper section of the catotelm (between 15 and 30 cm) for all the cores. In the Misten peat cores, correlation coefficients between mercury concentration and the humification were calculated. There was no significant correlation between Hg concentration and humification (for cores M1 and M4 \( r = -0.11 \), for core M2 \( r = 0.3 \) and for core M2 \( r = 0.07 \)).

### 3.3. Pb, Ti, Mn, Fe, Ca, and Mg concentrations

Major elements, Pb and Ti were investigated for only core M1. Calcium and magnesium concentrations are relatively constant in

Table 3: Comparison date, thickness and pollen zones for the Misten cores. Each pollen zone has a different characters AP (arboreal pollen) and NAP (non-arboreal pollen).

Fig. 3. The correlation of pollen zones in the four cores. The green color shows the acrotelm and the brown color is the catotelm. Black line is the concentration of Hg in the four cores.
Fig. 4. Profiles of bulk density (g cm\(^{-3}\)), ash content (%), humification (%), Ti and Pb concentration (mg kg\(^{-1}\)), Hg concentration (µg kg\(^{-1}\)), ratio Hg/humification, and pollen zones versus depth. (a) core M1, (b) core M2, (c) core M3, and (d) core M4.
the catotelm layer. In the uppermost section (catotelm layer) of this core, Ca and Mg concentrations increased to values > 2000 and 300 mg kg\(^{-1}\), respectively. The Mg/Ca ratio (\(\approx 0.23 \pm 0.11\)) is similar to the average rainwater in this area confirming that the Misten peat is ombrotrophic.

Titanium concentrations showed a large increase at catotelm–acrotelm boundary (Fig. 4a). Titanium concentrations were not correlated with Fe (correlation coefficients \(r = 0.34\)).

Iron is a major element susceptible to redox processes at the acrotelm–catotelm boundary (Gobeil et al., 1999) and Pb input may come from the surrounding watershed or from the atmosphere. Between 18 cm and the peat surface, the concentrations fall to 110 µg g\(^{-1}\) (Fig. 4a).

Lead values increase from the base of the core, and abruptly peak at 660 mg kg\(^{-1}\) within 5 cm under the acrotelm–catotelm boundary. They then decrease abruptly above this boundary but remained elevated at 400 mg kg\(^{-1}\). Lead concentration decreases to 5 mg kg\(^{-1}\) in surface (Fig. 4a). Manganese and iron concentrations are almost constant in the lower sections of core M1 (3 ± 1, 330 ± 60 mg kg\(^{-1}\), respectively). Manganese and iron concentrations increase in the upper sections, and decrease to the surface of the core M1 (Fig. 5).

3.4. Hg accumulation rates

In order to examine the historical record of Hg pollution over the last 1500 years, Hg accumulation rates, and Hg AR (µg m\(^{-2}\) y\(^{-1}\)) were calculated for the four cores studied (Fig. 6). Hg accumulation rates in M1 averaged -2 µg m\(^{-2}\) y\(^{-1}\) from 533 to 1611 AD. The mean values increase from 4 µg m\(^{-2}\) y\(^{-1}\) at the start of the Industrial Revolution (1891 AD) to > 170 µg m\(^{-2}\) y\(^{-1}\) at 1953 AD. Mercury accumulation rates increased to 115 µg m\(^{-2}\) y\(^{-1}\) (1965 AD), and decreased slightly to 111 µg m\(^{-2}\) y\(^{-1}\) (1975). Mercury accumulation rates increase to a maximum of 179 µg m\(^{-2}\) y\(^{-1}\) (1987 AD), followed by a decreased to the surface of the core (20 µg m\(^{-2}\) y\(^{-1}\), Fig. 6). In M2 and M3 cores, Hg accumulation rates remain constant at a mean value of 3 ± 1.4, 1.2 ± 0.4 µg m\(^{-2}\) y\(^{-1}\) respectively, from the base of M2 and M3 cores to 50 cm of depth, and increase to maximum values of 88 and 193 µg m\(^{-2}\) y\(^{-1}\), respectively. The Hg accumulation rates declined towards the top of the core to 5 and 38 µg m\(^{-2}\) y\(^{-1}\), respectively. In the core M4, Hg accumulation rates remained constant at a mean value of 1.4 ± 0.8 µg m\(^{-2}\) y\(^{-1}\) from 503 to 1603 AD. In the upper 25 cm of the core, Hg accumulation rates increased from 4 µg m\(^{-2}\) y\(^{-1}\) (1664 AD) to a maximum -120 µg m\(^{-2}\) y\(^{-1}\) (1930 AD), followed by a decline to 8 µg m\(^{-2}\) y\(^{-1}\) (2007 AD) at the surface (Fig. 6). There was a significant correlation between Hg AR in the four cores (\(r \geq 0.87\)).

4. Discussion

4.1. Effects of biogeochemical processes on Hg concentration

Previous work (e.g. Biester et al., 2003; Zaccone et al., 2009) suggested that Hg concentrations in peat bog cores may be affected by different biogeochemical processes (diagenetic processes, peat decomposition and humification). Similarly, Fe and Mn reactivity are influenced by similar processes (e.g. Steinmann and Shotyk, 1997). Some elements adsorbed on Fe and Mn oxides can be remobilized and redistributed during the redox processes (i.e. arsenic and phosphorus; Steinmann and Shotyk, 1997). In anoxic conditions, Fe and Mn oxides release Fe (II) and Mn (II) to the porewaters (Gobeil et al., 1999). These reduced forms will diffuse upward until they reach the oxic zone and become oxidized (Steinmann and Shotyk, 1997; Matty and Long, 1995). If Hg showed similar behavior then the maximum Hg concentration would be correlated with maximum in Fe and Mn concentrations in the upper layers of peat cores at catotelm–acrotelm interface.

In core M1, Fe and Mn concentrations were measured and compared with Hg concentration (Fig. 5). The maximum Hg concentrations in core M1, at 19 cm, are below the maximum Fe and Mn concentrations at 16–6 cm-depth. Normalizing Fe, Mn and Hg to a conservative element such as Ti showed that the maximum Hg/Ti ratio corresponded to the minimum in Fe/Ti and Mn/Ti ratios (Fig. 5). Such observation suggests that the Hg concentration profiles measured in the Misten bog were not affected by redox or diagenetic processes.

In a study on Patagonian cores, Biester et al. (2003, 2012) showed that Hg concentration is influenced by peat decomposition processes and mass losses, and suggested that Hg concentrations in peat do not solely reflect the variations in external Hg flux. However, Biester et al. (2012) recently showed using data collected from a peat bog in the Harz mountains, Germany, that “peat decomposition may have played only a minor role” in Hg distribution in the peat column illustrating the specificity of each site in preserving or not the Hg historical signal. The lack of correlation between humification and Hg concentrations also suggests that the peat decomposition is not playing a major role in Hg variability in Misten peat cores.

Others factors could also influence the Hg concentrations in peat. For instance, differences in the structure and morphology of the bog can indicate heterogeneous peat accumulation rates (Rydberg et al., 2010), as
observed in the Misten bog (Figs. 1c, 3). Despite the fact that the four cores were sampled in the most raised part of the bog, there were differences in peat accumulation rates between the four cores suggesting a recent heterogeneous growth of peat (Figs. 1c, 3). Similarly the peak Hg concentrations in each core are not located at the same depths. For example, the maximum Hg concentration for M1 was at 19 cm, for M2 at 27 cm, for M3 at 18 cm and for M4 was at 12 cm. However the change in Hg concentrations was similar as a function of age (Fig. 4).

In summary, biogeochemical processes do not appear to have affected the Hg profiles in Misten peat cores. The maximum Hg concentrations occur between 12 and 27 cm-depth and the change in Hg concentrations are similar across time and pollen zones (Fig. 4). The similar chronologies of Hg records in the four peat cores suggest that the atmospheric Hg deposition is the main process affecting the Hg profiles. Several studies showed that Pb is an immobile element in ombrotrophic peat bogs (e.g. Shotyk et al., 1998; Le Roux et al., 2005). In core M1, the correlation between Hg and Pb concentration (correlation coefficients \( r = 0.7 \)) showed similar chronology and distribution (Fig. 4a). The similarity between Hg and Pb profiles suggest that Hg is immobile as well in these cores.

4.2. Intra-site variability in Hg accumulation rates

Roos-Bacclarough and Shotyk (2003) compared both inter-site variability using a single peat core from the Etang de la Gruyere (EGR) and a signal core from the Tourbiere de Genevez (TEG) bogs, located 3.5 km from one another in Switzerland. The intra-site variability in absolute values of Hg AR exceeded the intra-core variability during the pre-industrial period between EGR, \( 1.0 \pm 0.3 \mu g \ m^{-2} y^{-1} \) (25% RSD), and TEG, \( 1.6 \pm 0.4 \mu g \ m^{-2} y^{-1} \) (30% RSD). During the industrial period (after 1700 AD) both the maximum and average Hg AR were also higher at TEG, \( 12.6 \pm 7.7 \mu g \ m^{-2} y^{-1} \) (61% RSD) than at EGR, \( 17.0 \pm 13.1 \mu g \ m^{-2} y^{-1} \) (77% RSD). However, relative increase factors were very similar between the two sites when comparing pre-Industrial to maximum (30\( \times \) vs. 28\( \times \)) and average Industrial period Hg accumulation (12\( \times \) vs. 11\( \times \)). Based on this we conclude that bog-specific characteristics prevent the comparison of absolute Hg deposition rates between bogs, but that relative increase factors obtained from different bogs are valid indicators of changes in Hg deposition.

The objective of the multi-coring approach taken in this study was to investigate the intra-site variability in Hg AR reconstructions on a scale of 10 to 100 m. Fig. 6 compares the Hg AR in the four cores. First, the Hg AR profiles agree fairly well between the four cores (\( r \geq 0.87 \), Table 4). The broad 20th century maximum Hg AR occurs in pollen zones 5 and 6 in all cores and at different locations with respect to the acrotelm–catotelm boundary. Intra-core and intra-site variability is summarized in Table 4. Pre-Industrial Hg AR from the 5th to the 14th century averaged \( 1.8 \pm 0.5 \mu g \ m^{-2} y^{-1} \) (27% RSD). Maximum Hg AR between the 1930s and the 1990s averaged \( 105 \pm 37 \mu g \ m^{-2} y^{-1} \) (36% RSD). Post-1990 declines in Hg AR stabilized around \( 23 \pm 10 \mu g \ m^{-2} y^{-1} \) (41% RSD). However, the core M2 maximum Hg AR of \( 53 \pm 33 \mu g \ m^{-2} y^{-1} \) and the core M1 pre-Industrial Hg AR of \( 2.4 \pm 1.5 \mu g \ m^{-2} y^{-1} \) were significantly different from the other cores (\( p < 0.02 \)). This shows that reconstructions of Hg AR that are based on a single peat core have a high statistical chance of showing core-specific values that are not representative of the bog as a whole (Bindler et al., 2004; Martinez Cortizas et al., 2012).

Taking the core M2, Hg AR maximum of \( 53 \mu g \ m^{-2} y^{-1} \) as an example, a single core study may deviate from the bog average (\( 105 \mu g \ m^{-2} y^{-1} \)) by as much as 100%. Despite these significant differences, the outlier observations on cores M2 and M1 do not exceed a variation of 2SD around the mean and were therefore retained in calculating the bog averaged Hg AR trends. The multi-coring approach taken in this study results in overall uncertainties associated with pre-Industrial, maximum 20th century, and post-maximum reconstructed Hg AR that are similar and around 30 to 40% RSD.

Potential factors that could contribute to this intra-site variation are micro-climatic variations affecting Hg deposition and soil re-emission.
1.4±1
2008 AD (23±10
the Misten cores, the recent Hg accumulation rate from 1990 to 200 AD to 950 AD for a Greenland peat bog (Shotyk et al., 2003), and Switzerland (Roos-Barraclough et al., 2002) and 27 ± 15
1800 and 1850 AD, the global production of Hg decreased from 1500 to 1800 AD in these mines was 150,000 tons (17% from the global present (Roos-Barraclarough et al., 2003; Biester et al., 2007). The average micro-topography and lateral run-off, or canopy effects when trees are present (Roos-Barrclough et al., 2003; Biester et al., 2007). The average relative increase factors between pre-Industrial and maximum Hg AR, 63 ± 31 (% RSD) and average anthropogenic period Hg AR and maximum Hg AR, 4.8 ± 1.7 (% RSD) for the Misten cores. The variations in relative increase factors between the four Misten cores are much larger than for the cited Swiss the Etang de la Gruyere (EGR) and the Tourbiere de Geneve (TEG) bogs, which may be related to the overall inhogeneous peat accumulation rates across time and space at Misten.

### Summary and intra-site comparison of reconstructed mercury accumulation rates (Hg AR, μg m⁻² y⁻¹) for the four Misten cores.

4.3. Comparison of the Misten bog with others sites

Hg accumulation rates reconstructed from the Misten peat cores are comparable to results obtained from other European bogs. The mean pre-Industrial Hg accumulation rate (before 1300 AD, 1.8 ± 0.5 μg m⁻² y⁻¹, 1SD) for M1, M2, M3 and M4 is similar to published values of 0.3–8 μg m⁻² y⁻¹ from 12,500 BC to 1300 AD for a Swiss peat bog (Roos-Barrclough et al., 2003; 0.3–3 μg m⁻² y⁻¹ obtained from 200 AD to 950 AD for a Greenland peat bog (Shotyk et al., 2003), and 1.4 ± 1 μg m⁻² y⁻¹ from 5700 BC to 1470 AD for 3 sites in Southern Ontario, Canada (Givel et al., 2004a, 2004b). Those studies suggested that Hg accumulation rates in several ombrotrophic bogs, during pre-Industrial period correspond mainly to natural Hg deposition.

During the Industrial revolution, the maximum Hg accumulation rates in the Misten peat bogs were within the range 90 to 190 μg m⁻² y⁻¹ (1930–1990 AD). This is in good agreement with the maximum values recorded in peat bogs in Switzerland (79 to 108 μg m⁻² y⁻¹) from 1911 AD to 1973 AD (Roos-Barrclough et al., 2002), Greenland and Denmark (164–184 μg m⁻² y⁻¹, Shotyk et al., 2003) in 1953 AD, Ontario peat bogs in Canada (55–141 μg m⁻² y⁻¹) from 1950 to 1960 AD (Givel et al., 2004a, 2004b), and Flanders Moss in Scotland (77–183 μg m⁻² y⁻¹) from 1923 to 1948 AD (Farmer et al., 2009). In the Misten cores, the recent Hg accumulation rate from 1990 to 2008 AD (23 ± 10 μg m⁻² y⁻¹) is similar to the 35 ± 5 μg m⁻² y⁻¹ in Switzerland (Roos-Barrclough et al., 2002) and 27 ± 15 μg m⁻² y⁻¹ for 4 Scottish cores (Farmer et al., 2009) but 2 times lower that what observed in recent peat layers of Czech Republic (Zuna et al., 2012).

4.4. Anthropogenic Hg sources to the Misten bog

The records of Hg accumulation rates found in the Misten bog are in good agreement with the history of the global production of Hg over the past 500 years reported by Hylander and Melli (2003) and of European coal production over the past 200 years (Rutledge, 2011) (Fig. 7). Mercury shows that Hg accumulation rates increase in cores M1 and M4 in parallel with the global production of Hg from 1500 to 1800 AD. Based on the data from these cores, during this period Hg accumulation rates increased from 2 to 28 μg m⁻² y⁻¹ in M1 and from 1 to 3 μg m⁻² y⁻¹ in core M4. This increase in Hg accumulation rate can be explained by Hg mining and metallurgy emissions in Almadén (Spain) and Idrija in Slovenia (Hylander and Melli, 2003). The total Hg production from 1500 to 1800 AD in these mines was 150,000 tons (17% from the global production in the last 500 years, Hylander and Melli, 2003). Between 1800 and 1850 AD, the global production of Hg decreased from 57,000 to 49,000 tons (Hylander and Melli, 2003), but the total Hg accumulation rates in Misten cores continued to increase (Fig. 7). This increase coincided with a maximum of European production of Hg (47,000 tons, 5% from the global Hg production) and a maximum Zn–Pb mining activity in Belgium (Dejonghe, 1998; Hylander and Melli, 2003). Average Zn ores contain ~10 mg kg⁻¹ of Hg (Hylander and Herbert, 2008). Coal production and industrial use became important in Europe (1.3 million metric tons per year) in 1817 AD and in 1830 AD (2.3 million metric tons per year) in Belgium (Rutledge, 2011). Therefore, Zn–Pb mining and coal burning may have been dominant source of Hg deposition between 1800 and 1850 AD. The increased Hg accumulation rates in the Misten peat cores between 1850 and 1915 AD can be explained by increased European coal production and use, and metal smelting and refinery (Pb and Zn) in Belgium. The European coal production increased up to 400 million metric tons per year in 1913 AD while that in Belgium was up to 25 million metric tons per year between 1900 and 1910 (Fig. 7). The smelter and refinery production (Pb and Zn) in Belgium increased by factor>100 from 1850 to 1913 (Fig. 7).

In the cores M1 and M4, the maximum Hg accumulation rates between AD 1930 and 1980 are good agreement with the maximum Belgian coal and smelter production (Fig. 7). Coal combustion, non-ferrous mining and refining were the dominant anthropogenic Hg sources from 1930 to 1970 (Shotyk et al., 2003, 2005). Mining activity decreased in Belgium after 1945 (Dejonghe, 1998; Schmitz, 1979). However, the import of Zn–Pb ores from worldwide locations to Belgium has always been larger than local production and fueled the metallurgical industries (Schmitz, 1979; Sonke et al., 2002). Smelter and refinery production of imported (Pb, Cu, and Zn) reached a maximum in 1976 (Fig. 7). This may explain the higher Hg accumulation rate in Misten peat cores (at 19 cm for M1 and at 12 cm for M4). The maximum Pb concentration in core M1 corresponds to the maximum Hg concentration, suggesting a common source of these elements. In the 20th century, coal combustion was the dominant anthropogenic source of both Hg (Lindberg et al., 1987; Shotyk and Krachler, 2010) and Pb (Shotyk et al., 2003, 2005) and is the most likely source for these two elements.

The reduction in Hg accumulation rates in the upper section of the peat cores between 1980 and 2008 follows the same trend as global and the European Hg/coal production. The decline of Hg AR after the 1980s may be linked to the introduction of Hg retaining filters in industrial process and the decline in coal consumption (Fig. 7). The main sources of Hg emissions in Belgium from 1980 to 2008 were chlorine plants, cement production, construction industry and mining and various industrial emissions (Mukherjee et al., 2004, 2008).

According to Ilyin et al. (2010), the atmospheric Hg deposition measured at 8 Belgian sites, from 1990 to 2008, demonstrate a declining trend. In 1991 (1987–1994 AD), the Hg accumulation rate was 67 μg m⁻² y⁻¹ over Belgium, close to that in cores M1 and M4. By 2009, atmospheric Hg deposition reduced to 19 μg m⁻² y⁻¹ (Ilyin et al., 2010), which again is in good agreement with reconstructed Hg AR at Misten of 18 μg m⁻² y⁻¹ in the surface peat layers (2007–2008 AD) and modeled data by EMEP (Ilyin et al., 2010, 2011; Travnikov et al., 2012). The modeled trend of Hg
deposition over Belgium (Travnikov et al., 2012) is in good agreement with the estimation of Hg AR by Mistant peat cores over the period 1990–2008.

5. Conclusions

The four Mistant peat cores recorded the historical evolution of Hg accumulation rates over the last 1500 years. The comparison between the pollen zones in the four cores of the Mistant peat bogs and the $^{210}$Pb–$^{14}$C dating in the cores M1 and M4 shows that the Mistant peat accumulation is rather heterogeneous. There is a good agreement between the AR chronologies of the four Mistant peat cores, as assessed independently by $^{14}$C–$^{210}$Pb combined chronologies and pollen timing zones. Our results show that despite different peat accumulation rates in the four cores, the Hg peaks in each core are always located in layers with the same age.

The multiproxy approach measured in core M1 (Fe/Mn ratio, and Pb profile) and the humification calculated for all cores show that Hg is not influenced by redox processes and is an immobile element in Mistant peat bog.

At the Mistant bog, pre-Industrial Hg accumulation rate averaged 1.8 ± 0.5 μg m$^{-2}$ y$^{-1}$ between 500 AD to 1300 AD. The highest Hg accumulation rates were observed during the 20th century (105 ± 37 μg m$^{-2}$ y$^{-1}$). The maximum Hg accumulation rates ranging from 90 to 200 μg m$^{-2}$ y$^{-1}$ are recorded between 1930 and 1980 AD. The Hg accumulation rate in the Industrial period seems to have been primarily caused by the regional domestic and industrial coal use and smelter and refinery activity (Pb, Cu, and Zn). This study shows the necessity of multi-coring of peat bogs to avoid biased absolute Hg AR reconstructions due to variations in natural biogeochemical and climatic processes. Estimated trends in Hg accumulation rates by peat cores and measured and modeled atmospheric fluxes measured by EMEP in Belgium were in good agreement for the period 1990–2008 with a decrease of a factor ~3–5 over this period.

Acknowledgments

This study was funded by the Walloon Region and the FNRS. This work is supported by research grants ANR-09-JCJC-0035-01 from the French Agence Nationale de Recherche and ERC-2010-StG_20091028 from the European Research Council. M. Allian receives funding from the government of Syria. Frederic Caudadap and Aurelie Lanzanova are thanked for their assistance with ICPMS analysis at GET.
