Abstract Globally, besides human medicine, an increasing amount of antibiotics as veterinary drugs and feed additives are used annually in many countries with the rapid development of the breeding industry (livestock breeding and aquaculture). As a result, mostly ingested antibiotic doses (30–90%) and their metabolites to humans and animals, as emerging persistent contaminants, were excreted together with urine and feces, and subsequently disseminated into environmental compartments in forms of urban wastewater, biosolids, and manures. More importantly, significant amount of antibiotics and their bioactive metabolites or degradation products were introduced in agro-ecosystems through fertilization and irrigation with antibiotics-polluted manures, biosolids, sewage sludge, sediments, and water. Subsequently, accumulation and transport of antibiotics in soil–crop systems, particularly soil–vegetable systems, e.g., protected vegetable and organic vegetable production systems, poses great risks on crops, soil ecosystem, and quality of groundwater- and plant-based products. The aim of this review is to explore the sources, fates (degradation, adsorption, runoff, leaching, and crop uptake), and ecological risks of antibiotics in agro-

ecosystems and possible food security and public health impacts. Three topics were discussed: (1) the occurrence, fates, and ecological impacts of antibiotics in agro-ecosystems, a global agro-ecological issue; (2) the potential ecological risks and public health threat of antibiotic pollution in soil–vegetable system, especially protected vegetable and organic vegetable production systems; and (3) the strategies of reducing the introduction, accumulation, and ecological risks of antibiotics in agro-ecosystems. To summarize, environmental contamination of antibiotics has become increasingly serious worldwide, which poses great risks in agro-ecosystems. Notably, protected vegetable and organic vegetable production systems, as public health closely related agro-ecosystems, are susceptible to antibiotic contamination. Occurrence, fate, and ecotoxicity of antibiotics in agro-ecosystems, therefore, have become most urgent issues among antibiotic environmental problems. Nowadays, source control, including reducing use and lowering environmental release through pretreatments of urban wastes and manures is a feasible way to alleviate negative impacts of antibiotics in agro-ecosystems.

1 Introduction

Broadly defined, antibiotics are organic substances that are produced through the secondary metabolism of living microorganisms or synthesized artificially or semi-artificially that can kill other microorganisms or inhibit their growth or metabolic activity via biochemical actions (Lancini and Parenti 1982; Thomashow and Weller 1995; Thiele-Bruhn 2003). Mass production and use of antibiotics in medicine and agriculture have existed and substantially benefited public health and agricultural productivity for over 60 years (Knapp et al. 2010). Nowadays, a wide variety of antibiotics are extensively applied worldwide as drugs for preventing or treating human, animal, and plant infections, or as feed additives for animals and fishes to prevent or treat diseases as well as growth promotion (Cromwell et al. 1996; Smith et al. 2002; McManus et al. 2002; Kumar et al. 2005a, b; Sarmah et al. 2006; Cabello 2006; Aust et al. 2008; Stone et al. 2009). It was estimated

that the total amounts of annual use of antibiotics had reached 100,000–200,000 tons worldwide (Wang and Tang 2010), including veterinary antibiotics and medical antibiotics. Among them, veterinary antibiotics are in the majority of the total amount used. For example, they approximately accounted for 70% of the total consumption in the USA and about 70% of them are used for nontherapeutic purposes (Sassman and Lee 2005; UCS 2001). Although the inclusion of antibiotics in feed for growth promotion in livestock production was banned in the European Union in 1998 (CEC 1998a, b) and Korea will cease the use of growth promotion antibiotics feed additives by 2012 (Kim et al. 2011), large-scale use of antibiotics in animal production is being widely adopted worldwide as drugs, particularly in the European Union, USA (Kolpin et al. 2002), China (Zhao et al. 2010), Southeast Asia, and Russia as feed additives or for prophylactic, metaphylactic, and therapeutic purposes (Hamscher et al. 2003; Sarmah et al. 2006). China is the largest country for production and use of antibiotics. In 2003, China produced 28,000 and 10,000 tons of penicillin and oxytetracycline (OTC), occupying 60% and 65% of the global total output (Yang et al. 2010a). On the other hand, antibiotics, as human medicines, have been extensively adopted in disease treatment globally, and their use frequency and dosage often surpass the actual need. Taking China for example, the proportion of antibiotics in drug prescription was over 70% in China, much higher than the proportion 30% in western countries, which reflected that the antibiotic misuse was more serious in China (Bruce et al. 2005).

With the rapid development of stockbreeding (e.g., livestock and poultry raising) and aquaculture (e.g., fishery), an unprecedented increment in used amount of veterinary antibiotics is undergoing. Among antibiotics, tetracyclines were the most commonly used, followed by sulfonamides and macrolides that accounted for approximately 90% of the total antibiotics used in the UK and more than 50% in Korea and Denmark (Kim et al. 2011). Subsequently, about 30–90% antibiotic doses to humans and animals, both unaltered and their metabolites, were excreted and released together with urine and feces after medication for incomplete absorption (Halling-Sørensen et al. 1998; Alcock et al. 1999; Winckler and Grafe 2001; Jjemba 2002a, b; Heberer 2002; Bound and Voulvoulis 2004; Phillips et al. 2004; Kumar et al. 2005b). Additionally, the amount rate of antibiotics excreted varies with the antibiotic species, the use dosage, as well as the type and the age of the animals (Katz 1980; Zhao et al. 2010). Furthermore, the overuse and abuse of antibiotics occur ubiquitous globally, which increases substantially the rates of excretion and environmental release (Smith et al. 2002). Some literatures showed that the excretion rates of some

antibiotics, e.g., chlortetracycline (CTC), sulfamethazine (SMZ), and tylosin (TYL) after medication, exceeded 50% (Montforts 1999; Winckler and Grafe 2001; EMEA 1994–2002; Arian et al. 2009a, b). Most antibiotics come from various sources will eventually enter in environmental compartments through different pathways. It is apparent that the readily water-soluble ones are inclined to spread broadly and quickly with the aid of water fluidity. Therefore, taking the large environment-release quantity and antimicrobial attributes of antibiotics into consideration, the ecotoxic risks of antibiotics in environment, particularly agro-ecosystems would be the key environmental and human health concerns, and should be paid more scientific attentions on.

Three main pathways for environmental release of antibiotics are included, i.e., feed additives for stock-breeding and aquaculture, human and veterinary drugs, and environmental release during production or use (Fig. 1). Some antibiotics are bioactive and recalcitrant after excretion (Bouwman and Reus 1994; Dolliver et al. 2008). As human medicine, antibiotics were released into environment media in forms of wastewater and biosolids,

and reached surface water and sediments via the release of effluents from sewage treatment plants (Hamscher et al. 2003; Giger et al. 2003; Göbel et al. 2004). All kinds of manures, as another important carrier of veterinary antibiotics, their transfer and seepage from manures to soil, surface, and groundwater also contribute the environmental release of antibiotics (Kim and Carlson 2005; Kim et al. 2005; Burkhardt et al. 2005; Kay et al. 2005). Moreover, water mobility will accelerate the environmental release and diffusion processes of some antibiotics, and consequently enlarged their geographic distribution and ecotoxicity in environmental compartments. Based on previous reports, environmental impacts of residual antibiotics include: (a) resistance evolution of pathogens and bacteria through long-time exposure, genetic variation, and transfer of antibiotic-resistant genes (ARGs), e.g., transferring resistance from nonpathogenic to pathogenic bacteria (Khachatourians 1998; Hirsch et al. 1999; Boxall et al. 2003); (b) human health impacts of antibiotic ingestion via animal- or plant-based food products and drinking water with antibiotic residues; (c) ecotoxic effects on nontarget organisms in aquatic environment and terrestrial environments, especially

Fig. 1 Sources, entrance pathways, fates of antibiotics in agroecosystems, and subsequent exposures to human

environmental microorganisms; and (d) ecological impacts on agro-ecosystems of introduced antibiotics through amending with manures (Wegener 1999; Kumar et al. 2005a; Boxall et al. 2006; Dolliver et al. 2007) and irrigated water. Recently, the occurrence of ARGs in various environmental components (sediments, soils, wastewater, and drinking water) has been detected, and their abundance in soils had increased significantly (Knapp et al. 2010). Thus, human being and animals are becoming subjected to a rising risk of superbug infection that cannot be treated with existing pharmacotherapy. To sum up, residual antibiotics in the environment may pose a serious threat to human health by antibiotic intake via food and drinking water, superbug infection, and so on.

Exposure and adverse effects of antibiotics to the water environment and terrestrial ecosystems have aroused great concern over the last decade. As a worldwide-growing concern issue, related studies dealing with occurrence, fate, and ecological risks of antibiotics have been conducted extensively, and the research data were updated and renewed quickly. There are more than 20 review articles on fates and ecological risks of antibiotics in Chinese (Zhang et al. 2005a, b, 2008a, b, c; Wang et al. 2006, 2007; Zhu and Song 2006; Kong and Zhu 2007; Zhou et al. 2007; Li et al. 2008; Wang and Tang 2010; Shi et al. 2010; Yang et al. 2010a; Wu et al. 2010a, b) and in English (Halling-Sørensen et al. 1998; Tolls 2001; Jjemba 2002a; Heberer 2002; Thiele-Bruhn 2003; Boxall et al. 2003; Kumar et al. 2005a; Sarmah et al. 2006; Kemper 2008; Snow et al. 2009; Ding and He 2010; Kim et al. 2011; Zhang and Li 2011) published in over the past decade. Many of them focused comments on the advances in exposure assessment in aquatic or terrestrial environment, fates (adsorption, translocation, and degradation), as well as ecological risks on ecosystems. However, few review literatures provided comprehensive summary that covered China and worldwide literatures and gave the overall and updated information on impacts of antibiotics in agro-ecosystem, particularly in protected vegetable and organic vegetable production systems (PV-OVPS).

Among agro-ecosystems, PV-OVPS are characterized by heavy application of organic fertilizer; therefore, they are much easier contaminated by antibiotics contained in manures, biosolids, and irrigation water. Organic fertilizer use as nutrient source and good soil amendment for PV-OVPS; in turn, PV-OVPS are suitable places to utilize or recycle animal wastes with respect to the environmental and economic benefits. By the end of 2009, China's organic cultivation area has developed increasingly in the past decade, up to 1.85 million hectares, listing the third in the world (Willer and Lilcher 2010). In addition, the acreage of protected horticulture has sustainedly develop in the past decade, reaching 3.5 million square hectometers (hm^2) in

2009 (Liu et al. 2009b) in China, ranking first globally. More than 90% protected facilities are used for vegetable production, particularly off-season vegetables (Fig. 2). Therefore, massive organic manure is usually fertilized into PV-OVPS. Apparently, the fates and ecological risks of antibiotics introduced in protected systems may differ from that of in open fields due to the special environmental conditions in protected facilities and planting intensity. The beneficial roles of organic manure played in protected vegetable production, including (a) increasing CO_2 emission and utilization by horticultural crops, (b) improving soil temperature to alleviate chilling stress, (c) providing nutrients, (d) ameliorating soil structure and avoiding succession cropping obstacle, and (e) alleviating soil secondary salinization caused by chemical fertilizer. Based on the above functions of organic manures, more and more organic manures were applied in protected agriculture. In some areas of China, it was estimated that the ratio of organic manure to total fertilizers used in protected facilities exceeded 60–87% (Zhang et al. 2005a, b; Zhao and Chen 2001). In addition, the fertilization rate of organic manure reached 100–150 tons/ hm^2 (Xiao and Yang 1997; Zhao and Chen 2001). However, residual antibiotics and some other contaminants (e.g., heavy metals) in organic manure from scaled stockbreeding farms discounted the benefits brought by organic manures (Yao et al. 2006). As a result, antibiotics accumulation and vegetable contamination occurred increasingly. Moreover, many relevant studies, especially in China and Germany, published and deepened the understanding on this topic in recent years. More importantly, no document available has reviewed the occurrence, fates, and ecological risks of antibiotics in agro-ecosystems (Snow et al. 2009) with highlights on PV-OVPS. Thus, collecting and summarizing the updated achievements in this field is helpful and necessary to impel future research. This review gives priority to the collection and comment on the novel documents issued after 2000 to supplement the existing review literatures.

2 Pathways of antibiotics entering agro-ecosystems

Agro-ecosystems, such as croplands or vegetable fields, are the most important terrestrial environment where antibiotics-containing animal manures or organic wastes were applied largely and repeatedly. In summary, two avenues of antibiotics entering agro-ecosystems are involved: firstly, fertilization with antibiotics-containing animal manures, biosolids, sewage sludge, and sediments (Jørgensen and Halling-Sørensen 2000; Díaz-Cruz et al. 2003, 2006; Göbel et al. 2004; Kemper 2008; Yang et al. 2010b); secondly, irrigation with antibiotic-polluted reclaimed water from sewage treatment plants, wastewater, surface water, or groundwater (Renew and Huang 2004; Gulkowska et al. 2007) since they have been frequently polluted by antibiotics (Kolpin et al. 2002; Christian et al. 2003; Giger et al. 2003; Göbel et al. 2004; Renew and Huang 2004; Gulkowska et al. 2007; Fig. 1). Simultaneously, produce, e.g., vegetables and grains, cultivated in antibiotic-contaminated agro-ecosystems may pose the potential threat to public health when high-level antibiotics were absorbed and accumulated. Currently, application of manures to agro-ecosystems is a common practice in many countries in the world, including China, as periodic measure, especially for PV-OVPS. However, antibiotics have just aroused attention as potential pollutants in the past two decades (Halling-Sørensen et al. 1998; Kümmerer 2001a). Although some processes have been known about the exposure, fates, and risks of antibiotics in environmental compartments, very limited information pertaining to those processes in agro-ecosystems was revealed so far, particularly organic agriculture and protected agriculture. Therefore, monitoring, assessing, and controlling the pollution status of water and organic fertilizers are helpful for predicting or reducing the amounts of antibiotics into agro-ecosystems and their potential human health impacts (Fig. 1). Also, it is necessary to study and to comprehensively evaluate the fate of antibiotics in dairy farms, from administration to excretion, waste collection, land application, and potential soil–water transport (Watanabe et al. 2010). More importantly, since fertilization and irrigation is carried out repeatedly and frequently year-by-year, long-term monitoring on fates of antibiotics in agro-ecosystems should be systematically examined.

2.1 Fertilization with animal manures and urban biosolids polluted by antibiotics

Residual antibiotics in medicated animal manures and urban biosolids contribute as the major sources of antibiotics entered in agricultural soils via fertilization. Therefore, monitoring, evaluating, and controlling the residual level of antibiotics in animal manures are an important link for reducing their accumulation and deleterious

impacts on agro-ecosystems. Generally speaking, antibiotic concentration in animal manure could be decreased significantly via composting and anaerobic fermentation treatment, which will favor the quantity reduction of antibiotic environmental exposure (Figs. 3 and 4). In order to evaluate the feasibility and efficiency of utilizing composting and anaerobic fermentation as control techniques to reduce environmental release of antibiotics, here the advances in treatment efficiency of composting and anaerobic fermentation on antibiotic removal from excretions were collected.

2.1.1 Concentrations of antibiotics in raw animal manures and urban biosolids

Many investigations have been conducted to examine the residual levels of antibiotics in animal dejecta and manures from large-scale livestock farms, mainly including slurry, dung, and manures of pig, cow, and chicken (Winckler and Grafe 2001; references in Table 1 and Kim et al. 2011). The residue levels for most antibiotics showed significant statistical differences among the sampling districts and the animal species (Zhao et al. 2010). Zhang et al. (2008a, b, c) showed that the residue level of selected antibiotics varied in sequence of pig manure > chicken manure > cow manure, and the antibiotics residues were generally higher in animal manures from industrial-scale farms than in those from farmer's households. Apart for animal excreta, residues of these substances in the farm dust present a new source of health hazard for farmers (Hamscher et al. 2003). Hamscher et al. (2003) detected up to five different antibiotics in 90% of dust samples collected during two decades from the same piggery. The total amounts were up to 12.5 mg/kg dust. The results suggested that dust from the farm is a route of entry for veterinary drugs in the environment and risks may arise from the inhalation of dust contaminated with antibiotics.

Urban biosolids are a source of antibiotic contamination for the agro-ecosystem because these substances are usually employed in agriculture. Biosolids refer to solid, semisolid, and liquid residues that are generated during the treatment of

Fig. 3 Typical scaled livestock breeding in China

Fig. 4 Waste treatment of scaled livestock breeding

domestic sewage in treatment works. Antibiotic residues have been frequently detected in sewage, activated sludge, digested sludge, and urban biosolids (Zhang and Li 2011); the presence

of antibiotics in these materials has become an increasingly recognized environmental risk as well (Halling-Sørensen et al. 1998; Hirsch et al. 1999; Jørgensen and Halling-Sørensen 2000). Some of the antibiotics can maintain residual activity in biosolids for a long time (Summer 2000). Zhang and Li (2011) summarized the latest information on occurrence, transformation, and fate of antibiotics in wastewater treatment plants based on more than 90 papers published.

2.1.2 Antibiotic concentrations in treated animal manures and urban biosolids

Whether or not there is pretreatment before environmental discharge or agricultural utilization determines the final residual concentrations of antibiotics in animal manures to some extent. Composting, anaerobic, and aerobic digestion

Table 1 The reports on antibiotic content in animal excreta

Sites	Antibiotics species	Sample description	Average concentration	Reference
Germany	TC, CTC	Liquid pig manure	0.1–4 mg/kg	Hamscher et al. (2002)
Germany	TYL, TC, SMZ, CAP	10–15 Dust samples each year during 1981–2000 from piggery	Detected in 90% samples, 0.19–12.5	Hamscher et al. (2003)
Seven provinces, China	OTC, TC, CTC	32 Pig and 23 chicken manure samples	Pig manure: 9.09 for OTC, 5.22 for TC, 3.57 for CTC; chicken manure: 5.97 for OTC, 2.63 for TC, 1.39 for CTC	Zhang et al. (2005a, b)
Tianjin, China	OTC, TC, CTC, Doxycycline, SDZ, SDM, SCP, SMZ, SDO, Furazolidone, CIP, Pefloxacin, CAP	9 Pig manures and 11 chicken manures	0.3–173 µg/kg	Hu et al. (2008)
Zhejiang province, China	OTC, TC, CTC	93 Pig, cow and chicken manure samples	3.1 for OTC, 1.57 for TC, 1.8 for CTC	Zhang et al. (2008a, b, c)

Tianjin, China	OTC, CIP, CTC, SMZ, SDO, SCP, CAP, OFL, PEF, CIP, LIN	Winter manures and summer manures	Winter manures: 0.1–183.5; summer manures: n.d.–29.3	Hu et al. (2010)
Eight provinces, China	FQ, SDM, TC	61 Pig, 54 chicken and 28 cow dung samples	Pig and cow dung: up to 34 and 30 CIP, 33 and 47 EFL, 59 and 60 OTC, 21 and 28 CTC; chicken dung: up to 99 fleroxacin, 225 norfloxacin, 46 CIP, 1,421 EFL	Zhao et al. (2010)

AMX amoxicillin, AOC aureomycin, CAP chloramphenicol, CTC chlortetracycline, CIP ciprofloxacin, EFL enrofloxacin, FQ fluoroquinolones, LIN lincomycin, LSM lincosamides, OFL ofloxacin, OTC oxytetracycline, PEF pefloxacin, SA sulfanilamide, SDZ sulfadiazine, SDM sulfadimidine, SMM sulfamonomethoxine, SCP sulfachloropyridazine, SMR sulfamerazine, SMT sulfameter, SDM sulfadimethoxine, TC tetracycline, TYL tylosin; n.d. not detected

are well-established approaches for reducing the amount of antibiotics in animal manures (Kolz et al. 2005; Arikan et al. 2006, 2007, 2008; Stone et al. 2009; Mohring et al. 2009; Bao et al. 2009). The degradation rates of antibiotics during composting, anaerobic, or aerobic digestion varied with the species of antibiotic, the type of livestock manures, and the composting conditions. Moreover, removal technologies of antibiotics in sewage treatment plants were actively developed in the European Union and the USA (Kim et al. 2005; Castiglioni et al. 2006; Vieno et al. 2006; Xu et al. 2007a,b). A variety of commonly used antibiotics are persistent in the environment. Although some methods, including adsorption, biodegradation, disinfection, and membrane separation were developed to remove antibiotic in different wastewater treatment processes of municipal wastewater treatment plants, many antibiotics cannot be removed completely in wastewater treatment processes and would enter into environment via effluent and sludge (Ternes 1998; Zhang and Li 2011). On the other hand, antibiotics present may impact the efficiency of digestion and their degradation during treatment for their antimicrobial properties. Previous studies showed that antibiotics or metabolites in manure had negative effects on treatment systems such as anaerobic digesters (Poels et al. 1984) and nitrifying systems (Campos et al. 2001). However, Kakimoto et al. (2007) found that amoxicillin did significantly decrease the composting of human feces even at only 10 µg/g dry weight. In summary, source reduction through pretreatments is an effective method to control environmental release and contamination by antibiotics, but relevant techniques should be fully developed to enhance their efficiencies.

2.2 Irrigation with water polluted by antibiotics

Antibiotics could enter aquatic environment through urban sewerage systems and wastewater of livestock breeding (Fig. 5), and runoff and leaching from terrestrial ecosystems. Certainly, antibiotics in aquatic environment could be transported into agro-ecosystems via irrigation and sedi-

Fig. 5 Wastewater treatment of scaled livestock breeding

ment utilization. As early as 1980s, high-level antibiotics detected in UK's river water in 1960s were reported (Watts et al. 1982). In addition, US survey revealed that a number of antibiotics were detectable in 27% of 139 rivers at concentrations of up to 0.7 µg·L⁻¹ (Kolpin et al. 2002). Up to now, antibiotics occurred widespread in surface waters (Lindsey et al. 2001; Christian et al. 2003; Managaki et al. 2007) and groundwaters (Sacher et al. 2001; Lindsey et al. 2001; Kolpin et al. 2002; Hamscher et al. 2005; Focazio et al. 2008), particularly the persistent, soluble species, e.g., CTC (Kolpin et al. 2002). CTC was found in 2.4% of the 84 surface water samples with the maximum concentration of 0.69 µg/L by Kolpin et al. (2002). Many reports had detected antibiotic pollution in water bodies in Asia (Xu et al. 2007a, b; Gulkowska et al. 2007) and Europe (Golet et al. 2002; Christian et al. 2003; Stolker et al. 2004; Lindberg et al. 2005; Tamtam et al. 2008), particularly for water from sewage treatment plants (Alcock et al. 1999; Lindberg et al. 2005; Castiglioni et al. 2006; Vieno et al. 2006; Xu et al. 2007a, b; Pedrouzo et al. 2011). Giger et al. (2003) detected antibiotics in hospital and municipal wastewater. Gulkowska et al. (2007) detected tetracycline (TC), erythromycin, norfloxacin, and trimethoprim in Hong Kong coastal waters. Managaki et al. (2007) reported that the veterinary antibiotics, e.g., erythromycin, trimethoprim, and various sulfonamides, were detected in the Mekong Delta in Vietnam. Additionally, the highest concentrations in both water and sediment samples occurred in winter and sediment samples had greater detection frequencies and higher concentrations than water samples (Kim and Carlson 2007). This might be attributed to the seasonal changes of antibiotic concentrations from sewage treatment plants and hospitals (Pena et al. 2010). In view of the frequent occurrence and accumulation of antibiotics in natural water in global areas; thereafter, the species and rate of antibiotics entering agro-ecosystems by irrigation may tend to increase.

3 Fates of antibiotics in agro-ecosystems

Agro-ecosystems are the ideal places to employ and utilize animal manures. However, high anthropogenic input quantity and low harmless treatment rate of animal manures unavoidably result in continuous accumulation of antibiotics in agro-ecosystems through repeated fertilization. Taking China as an example, annual production of animal wastes in China had climbed up to 2–3 billion tons and only 50% was utilized. More importantly, the harmless treatment rate of animal wastes is just about 11% (Zhang 2008). After entering agricultural soil of antibiotics, several interrelated processes were involved, including degradation (Kreuzig and Höltege 2005), adsorption (Rabølle and Spliid 2000), transport (leaching and runoff) (Blackwell et al.

2007), and plant uptake (Migliore et al. 1996; Kumar et al. 2005a; Boxall et al. 2006; Dolliver et al. 2007). The active ingredients in the upper soil layer might either accumulate in soil or be absorbed by crops, or be readily available for transport into surface and groundwater through leaching and overland flow runoff (Jongbloed and Lenis 1998). All dynamic processes of antibiotics in soils are closely interrelated and driven by crop, soil microorganism, water, and anthropogenic activities, which will ultimately determine the spatial–temporal distribution and environmental impacts of antibiotics.

3.1 Soil accumulation

Soil is a habitat of indigenous antibiotics produced by soil microorganisms (Gottlieb 1976; Thomashow et al. 1997). Topp (1981) found that less half-soil actinomycetes isolated were able to synthesize antibiotics, also in situ rhizosphere, the background level of antibiotics was up to 5 µg/g soil (Lumsden et al. 1992; Shanahan et al. 1992). Some exogenous antibiotics incorporated soil through fertilization and irrigation were persistent and cumulative, which resulted in an increasingly residual concentrations ranged from a few micrograms up to grams per kilograms

(see Table 2; Thiele-Bruhn 2003). Many countries had detected the antibiotic residues in soils (Boxall 2004; Hamscher et al. 2005; Martinez-Carballo et al. 2007). As previously reported, TC could persist in soil for over 1 year (Zuccato et al. 2000), and only a moderate degradation of various TCs occurred within 180 days (Hamscher et al. 2002). Hamscher et al. (2002) detected the concentration of TC up to 0.3 g/kg in farmland soil fertilized with liquid manure. Also, 9.5 µg/kg CTC in the upper 10 cm soil from eight fields manured with animal slurry 2 days before sampling were detected (Kolpin et al. 2002). Zhang et al. (2008a, b, c) found that about 93%, 88%, and 93% of surface soils (0–20 cm) applied manure contained OTC, TC, and CTC, and their soil residues were 38, 13, and 12 times as high as those soils without manure application. Martinez-Carballo et al. (2007) detected CTC, enrofloxacin, and ciprofloxacin in arable Austrian soils. In addition, half-lives of some antibiotics in soils were examined (Schlüsener and Bester 2006; Accinelli et al. 2007).

3.2 Adsorption and degradation

Soil adsorption is the main physicochemical mechanism that prevents the antibiotics from leaching or runoff to some extent.

Table 2 Antibiotics concentration in soils

Site	Antibiotics species	Concentration detected	Sample description	Reference
Germany	CTC, TC	86.2, 198.7, 171.7 mg/kg TC; 4.6–7.3 mg/kg CTC	0–10, 10–20 and 20–30 cm soils	Hamscher et al. (2002)
Zhejiang, China	OTC, CTC	OTC, 0.44–1.23; CTC, 0.44–1.56 mg/kg	0–20 cm soil	Wang and Han (2008)
Zhejiang province, China	OTC, TC, CTC	0.64 for OTC, 0.65 for TC; 0.56 for CTC mg/kg	48 Surface 0–20 cm and subsurface 20–40 cm soils	Zhang et al. (2008a, b, c)

Guangdong, China	TCs, SMDs, quinolones	242.6, 33.3–321.4, 27.8–1,537.4 µg/kg	Vegetable field soils	Li et al. (2011)

CAP chloramphenicol, *CTC* chlortetracycline, *CIP* ciprofloxacin, *EFL* enrofloxacin, *LIN* lincomycin, *LOM* lomefloxacin, *NOR* norfloxacin, *OFL* ofloxacin, *OTC* oxytetracycline, *PEF* pefloxacin, *SMD* sulfonamides, *SMZ* sulfamethazine, *SDO* sulfadoxine, *SCP* sulfachloropyridazine, *SDZ* sulfadiazine, *SMR* sulfamerazine, *SMT* sulfameter, *SDM* sulfadimethoxine, *TC* tetracycline, *n.d.* not detected

The extent of antibiotic adsorption to soils depends on the antibiotic species present and soil properties including pH, organic matter content, and the concentration and type of divalent cations present, regardless of soil type (Rabølle and Spliid 2000). Dissolved organic matter decreased sorption of antibiotics to clay by increasing their mobility (Kulshrestha et al. 2004). Sorption to sterile manure, compost, and humic acid was determined to be strongly affected by contact time and pH. Kurwadkar et al. (2007) also found a strong pH dependency for sorption of sulfathiazole and SMZ to three sand and loam soils. TCs are known to bind strongly to soil particles, due to their ability to form complexes with doubly charged cations (e.g., Ca^{2+} ; Tolls 2001; Hamscher et al. 2002). Sassman et al. (2007) also studied sorption and degradation of TYL and its degradation products. Residues of OTC, TC, and CTC correlated positively to soil clay content. The more porous the soil texture, the more antibiotics are liable to transport and accumulate in the subsurface horizons of many soils (Zhang et al. 2008a, b, c). Soil-contained antibiotics may degrade completely or partially of the parental compound (Kümmerer 2001b) through three degradation behaviors (Schlüsener and Bester 2006) driven by biodegradation and photodegradation. The photodegradability of antibiotics in aqueous and soil environments is an important factor in environmental fate. Thiele-Bruhn and Peters (2007) observed significant photodegradation of various TC and sulfonamides in sterile water and soil surfaces.

3.3 Leaching and runoff

Mobility and transport of accumulated antibiotics are important processes involved in environmental issue, which may evoke when irrigation and precipitation occur. Leaching of antibiotics into deeper soil or into groundwater depended on the adsorption strength of the drugs in topsoil (Hamscher et al. 2002). Stoob et al. (2007) conducted a field study of sulfonamide runoff from cropland to surface water. Results suggested a worst-case scenario of 0.5% runoff loss for sulfonamides. Wehrhan et al. (2007) reported extensive column studies of SDZ leaching. Kay et al. (2005) examined the antibiotics concentrations in the overland flow in an irrigated arable land after 4-h pig slurry application. They found that sulphachloropyridazine and OTC was detectable in runoff from the tramline plot at a peak concentration of 0.7 and 0.072 mg/L. However, TYL was not detected. Blackwell et al. (2007) determined OTC fate in soil and very low concentrations were detected in surface runoff but not in soil pore water.

3.4 Crop uptake

High-level accumulation of antibiotics in food crops may raise potential human health concerns through food chain. Previous studies showed that crops could absorb from antibiotics-polluted soils or manure-amended soils (Table 3).

Table 3 Antibiotic concentration in crops

Site	Crop species	Antibiotics species	Concentration detected	Reference
Italy	Millet, pea, corn and barley	SMZ	1,000–2,000 $\mu\text{g/kg}$ in foliage and root	Migliore et al. (1996)
Italy	Weed species: <i>Amaranthus retroflexus</i> L., <i>Plantago major</i> L., <i>Rumex acetosella</i> L.	SDM	981–6,065 $\mu\text{g/kg}$	Migliore et al. (1997)
USA	Corn	SMZ	<1.06 mg/kg	Kumar et al. (2005a)
China	Alfalfa (<i>Medicago sativa</i> L.)	OTC	OTC absorbed by alfalfa, and the uptake inhibited by 2,4-dinitrophenol and Hg^{2+}	Kong et al. (2007)
USA	Corn	SMZ	0.9–1.2 mg/kg	Dolliver et al. (2007)
USA	Wheat	CTC, SDZ	Root 1.1 and 0.5 for CTC and SDZ; 0.043 of CTC was detected in wheat grain	Grote et al. (2007)
USA	Soybean	Carbamazepine, diphenhydramine, fluoxetine	Carbamazepine, triclosan accumulated in root tissues and above ground parts; diphenhydramine and fluoxetine	Wu et al. (2010a, b)

CTC chlortetracycline, OTC oxytetracycline, SMD sulfonamides, SMZ sulfamethazine, SDZ sulfadiazine

Generally, the uptake and effects on plants varies considerably between reports and depends on the antibiotic and plant species (Migliore et al. 1995; Kumar et al. 2005a; Dolliver et al. 2007). Some antibiotics, e.g., TYL, could not be absorbed by corn, green onion, and cabbage (Kumar et al. 2005a) because of their large molecular weight. Although the maximum residue value for antibiotics in animal-based products has been established, the limit for antibiotics in plant-based products is absent yet (JECFA 2006).

4 Effects of antibiotics in agro-ecosystems

Nowadays, antibiotics are being considered as ubiquitously occurring persistent contaminants in agro-ecosystems, and their ecological risks are a growing problem with respect to agro-environmental quality. Many antibiotics are persistent with long half-lives in soils. Long-term accumulation of persistent antibiotics and their metabolites in agro-ecosystems are bioactive and ecotoxic to soil microorganisms and crops, particularly bacteria (Baguer et al. 2000). Here, we summarized the research advances in ecotoxicity of antibiotics in agro-ecosystems, including soil microorganisms, soil enzyme activity, and crops.

4.1 Impacts on soil microorganisms and soil enzyme activity

Environmental antibiotics are still bioactive chemicals that are potentially hazardous to soil bacteria and other organisms (Baguer et al. 2000). The side effects of antibiotics on nontarget soil organisms are the issues of most concern in ecological risks assessment since they are highly effective and bioactive substances. A number of soil microbiological parameters, including microbial biomass and basal respiration, have been suggested as possible indicators of soil environmental monitoring programs (Yao et al. 2000; Winding et al. 2005). Degraded products of antibiotics also exhibited toxicity to microorganisms (Ge et al. 2010). In general, residual antibiotics in the soils may possibly assist in developing antibiotic resistant microbial populations (Witte 1998; Morris and Masterton 2002), microbial activity (Jjemba 2002a, b), and alter soil microbial constitution and functions. The occurrence of ARGs in various soil bacteria has been detected and their abundance in soils had increased significantly (Knapp et al. 2010). Generally speaking, there is limited information available on the direct effects of these drugs on soil biota, particularly those living in rhizosphere. Furthermore, previous reports on the effects of pharmaceutical antibiotics on soil microorganisms are inconsistent (Thiele-Bruhn and Beck 2005; Kong et al. 2006; Zielezny

et al. 2006; Kotzerke et al. 2008). Ding and He (2010) summarized the effect of antibiotics in the environment on microbial populations.

Diao et al. (2004) reported that apramycin inhibited soil bacteria growth significantly. Previous studies showed that oxidative stress induced by fenpropimorph and fenhexamid could be alleviated by arbuscular mycorrhiza (Campagnac et al. 2010), and arbuscular mycorrhiza benefited for the detoxification of xenobiotics, a pharmaceutical paracetamol (Khalvati et al. 2010). However, the impacts of antibiotics on formation and function arbuscular mycorrhizal symbiosis were little investigated up to now. Kotzerke et al. (2011) investigated the effects of manure containing different concentrations of the antibiotic amoxicillin on microbial community function in soils over an incubation time of 18 days. Soil potential nitrification rate was not significantly affected. Currently, there is lack of the understanding on ecotoxic impacts of antibiotics on soil ecology, particularly growth, community structure, function, and diversity. In addition, some beneficial rhizosphere microorganisms, like arbuscular mycorrhizal fungus and rhizobium have not been investigated yet till now.

The impacts on soil organisms of antibiotics will certainly modify enzyme activities and soil biochemical processes. Wei et al. (2009) showed that the presence of TC significantly disturbed the structure of microbial communities and inhibited soil microbial activities in terms of urease, acid phosphatase, and dehydrogenase. The antibiotics, including CTC, TC, TYL, SMX, SMZ, and trimethoprim, inhibited soil phosphatase activity during the 22 days' incubation. Significant effects on soil respiration were found for the two sulfonamides (SMX and SMZ) and trimethoprim, whereas little effects were observed for the two TC and TYL (Liu et al. 2009a). OTC decreased the urease, sucrase, phosphatase, hydrogen peroxidase, and microbial biomass nitrogen in rhizosphere of wheat, and increased the microbial biomass carbon (Yao et al. 2010).

4.2 Phytotoxicity

Phytotoxicity of antibiotics had been examined through seed germination experiment (Liu et al. 2009a, b) and plant growth tests (Wei et al. 2009), varying between plant species and antibiotic compounds (Batchelder 1982; Jjemba 2002a; Farkas et al. 2007; Liu et al. 2009a, b; see Table 4). The earlier results dealing with the effects of antibiotics on plants were reviewed by Jjemba (2002b) and Thiele-Bruhn (2003). Three hundred milligram per liter sulphadimethoxine (SDM) in agar and soil-based laboratory systems significantly reduced root, stalk, and leaf growths of millet, pea, corn, and barley (Migliore et al. 1996). These authors identified bioaccumulation as the mechanism causing the

Table 4 Phytotoxicity of antibiotics

Sites	Plant species	Antibiotics species	Impacts or concentration detected	Reference
Italy	<i>Cucumis sativus</i> L., <i>Lactuca sativa</i> L., <i>Phaseolus vulgaris</i> L., <i>Raphanus sativus</i> L.	EFL	Modifying the length of primary root, hypocotyl, cotyledons and the number/length of leaves	Luciana et al. (2003)

phytotoxic response since concentrations as high as 1,000 and 2,000 mg/kg SDM were reported in the foliage and root materials, respectively (Migliore et al. 1996). Kong et al. (2007) found that 0.002–0.2 mM OTC significantly inhibited the growth of alfalfa at 61–85% and they suggested that OTC uptake into alfalfa is an energy-dependent process. Currently, limited studies have been conducted to investigate the phytotoxicity of antibiotics to crop plants (Migliore et al. 1998, 2003; Kong et al. 2007). When grown in CTC-treated soil, a significant increase in the activities of the plant stress proteins glutathione S-transferases and peroxidases was observed in maize plants, but not in pinto beans (Farkas et al. 2007). Boxall et al. (2006) found that carrot and lettuce growth were inhibited by spiking at a concentration of 1 mg antibiotic per kilogram soil. Genotypic differences in responses of wheat to OTC were found among 63 wheat cultivars tested. The most sensitive cultivar to OTC with the EC₅₀ value of 1.25 mg/L, and the most insensitive cultivar to OTC with the EC₅₀ value of 54.21 mg/L, and chlorophyll contents in leaves of the two wheat cultivars tested decreased with the increase of OTC concentrations (Xie et al. 2009).

5 Risks related to antibiotics in soil–vegetable systems, particularly PV-OVPS

5.1 Use necessity, benefits, and antibiotic risks of organic fertilizer in PV-OVPS

Recently, the environmental fates and impacts of antibiotics as emerging pollutants in PV-OVPS have been paid growing attention on (Shi et al. 2010; Hu et al. 2010). In order to balance nutrients and to overcome continuous cropping obstacle dysfunctions, vegetable production in PV-OVPS needs to apply more organic manures than other agro-ecosystems. More importantly, organic fertilizer as the principal nutrient source and soil amendments for PV-OVPS is supplied repeatedly and annually in large scales. Consequently, antibiotics were introduced PV-OVPS together with organic fertilizer in large quantity and possibly accumulated up to a high level both in soil, groundwater, and vegetables. Currently, this is unavoidable since the majority of organic fertilizer could only originate from large-scaled livestock farms where antibiotics were intensively used. Antibiotic con-

Table 5 Antibiotics absorption and accumulation of vegetables

Sites	Plant species	Antibiotics species	Concentration detected	Reference

CAP chloramphenicol, *CTC* chlortetracycline, *CIP* ciprofloxacin, *EFL* enrofloxacin, *LIN* lincomycin, *OFL* ofloxacin, *OTC* oxytetracycline, *PEF* pefloxacin, *SMZ* sulfamethazine, *SDO* sulfadoxine, *SCP* sulfachloropyridazine, *TC* tetracycline, *TYL* tylosin

tamination of PV-OVPS may impact the productivity and quality of vegetables. Additionally, water contamination by antibiotics may affect protected vegetable production in hydroponics. Study results indicated that full nutrient solution spiked into milligrams per liter of antibiotics (e.g., CTC) inhibited growth vigor seriously (Cui et al. 2008). Vegetables are ready-to-eat freshly food crops, a kind of principal food. Uptake of antibiotics by vegetables contributes to human ingestion of antibiotics (Batt et al. 2006; Ye et al. 2007a, b), which may pose more serious health risks than other crops. Other major risks of introducing these substances into PV-OVPS are the development of resistant pathogens and adverse impacts on soil beneficial microorganism that are closely correlated to vegetable health.

5.2 Antibiotic pollution of soil–vegetable systems, particularly PV-OVPS

Recently, contamination of antibiotics in soil–vegetable systems was given serious attention worldwide (Table 5)

particularly in China (Shi et al. 2010; Hu et al. 2010). Antibiotic pollution in agro-ecosystems, particularly PV-OVPS, is becoming an intractable environmental problem.

5.2.1 Soil, groundwater pollution

Zhao (2007) detected some kinds of antibiotics in all soils from vegetable fields in pig farm, common vegetable fields, nonpollution vegetable fields, and green vegetable fields in Pearl River Delta. Results showed that antibiotic levels in the soils of vegetable field in pig farm, common vegetable field, nonpollution vegetable field, and green vegetable fields presented a decrease trend. Shi et al. (2010) and Hu et al. (2010) firstly put forward the antibiotic pollution issues stemming from organic manures in PV-OVPS in China. Hu et al. (2010) firstly investigated the occurrence and seasonality of antibiotics in OVPS, including manure, soil, vegetables, and groundwater. Seasonality of concentration change of antibiotics in manure and groundwater (Hu et al. 2010) were found, which depended on the application

season of manure (Hamscher et al. 2000; Hu et al. 2010). Arable lands were applied in spring with a summer-high concentration, while organic bases were fertilized in winter with a winter-high concentration. Tai et al. (2010) found quinolone antibiotics in soils from vegetable field chronically fertilized with manure in subtropical area where high frequency are detected, decreasing with the increase of soil depth, and residual concentrations varied with the vegetable species. For long-term manure-amended soils planting vegetables, the soil contamination of antibiotics was significant (Li et al. 2009b; Tai et al. 2010). Hu et al. (2010) detected nanograms per liter antibiotics in groundwater of OVPS. Li et al. (2011) has revealed an alarming condition of antibiotics in vegetable farmland soil of the Pearl River Delta, southern China. They found that the highest antibiotic concentrations were observed mainly in vegetable farmlands affiliated with livestock farms and the composition and concentration of antibiotics in soil were correlated with vegetable species. More importantly, chlortetracycline, sulfameter, and quinolones in some soils exceeded the ecotoxic effect trigger value (100 µg/kg) set by the Steering Committee of Veterinary International Committee on Harmonization (Li et al. 2011).

5.2.2 Vegetable pollution by antibiotics

Unintentional high-level introduction of antibiotics together with organic fertilizer are the fundamental inducement (Li et al. 2009a). Relevant scientists are trying to enrich the understanding to accumulation of antibiotics in vegetables, and the possible human health risks via food chain. Some results showed that vegetables could absorb, transport, and accumulate antibiotics in edible parts, such as lettuce (Boxall et al. 2006; Dolliver et al. 2007; Cui et al. 2008), potato (Dolliver et al. 2007), green onion (Kumar et al. 2005a), cabbage (Kumar et al. 2005a), carrot (Boxall et al. 2006), and leek (Wang and Han 2008). The distribution of antibiotics in vegetable organs was in the sequence leaf>stem>root (Hu et al. 2010), and the antibiotic levels in vegetable samples in winter were significantly higher than those in summer. Additionally, uptake of antibiotics by vegetables differed with antibiotic and vegetable species (Boxall et al. 2006). Overall, these works laid the sound foundation for understanding ecological risk of antibiotics and their potential adverse effects on human health by food chain.

6 Research prospects

6.1 Fates and ecological risks of antibiotics in agro-ecosystems: a global agro-ecological issue

Occurrence of antibiotics in animal excretions and environmental media, e.g., surface water, groundwater and soil, had

been widely investigated and acknowledged. Furthermore, it has been widely accepted that antibiotics are emerging, broad-spectrum bioactive and persistent organic contaminants. Thus, it is inevitable to pollute the farmlands through repeated fertilization and irrigation. Accumulated antibiotics in agro-ecosystems may pose serious threat to soil ecosystem when soil accumulation occurs. Nowadays, many studies have been conducted to investigate the dynamics of antibiotics in agro-ecosystems, including soil persistence, soil adsorption, degradation, transport, and crop uptake (particularly vegetables), and a few valuable data have been presented. Some negative impacts of antibiotics on agro-ecosystems were preliminarily revealed, including (a) inhibition seed germination and crop growth, (b) inhibited microbial activity and soil enzymatic activity, (c) antibiotic accumulation in crop biomass, and (d) leaching and runoff diffusion into groundwater and groundwater. However, there are scarcity in-depth systematical investigations on some aspects, e.g., long-term effects of antibiotics on soil microorganisms, soil accumulation and crop absorption, and human health impacts. Furthermore, the environmental impacts of their metabolites of antibiotics have been little investigated, although they are considered to be bioactive. Thus, clarifying the migration processes, fates, and ecological impacts in agro-ecosystems is a key link to understand the environmental effects of antibiotics comprehensively. Monitoring and controlling of antimicrobial contaminants in arable lands and their crops will be of importance for preventing agro-ecosystems and consumers from damage.

6.2 Fates and ecological risks of antibiotics in PV-OVPS: the urgent agro-ecological issue

Vegetables, the indispensable staple produce providing humans with many beneficial substances, are readily contaminated by nitrate, heavy metals, pesticides (Liu et al. 2009b), and antibiotics during cultivation (Hu et al. 2010). The contamination of antibiotics for protected vegetables and organic vegetables has become an urgent problem (Smukler et al. 2008; Siderer et al. 2005). The urgency of public damage of vegetable pollution is based on considerations below: (1) heavy acquirement and accumulation of harmful substance during short growth period, (2) high proportion of edible parts, and (3) short-term storage and fresh consumption. All these determine that there is larger quantity and quicker transportation of pollutants through vegetable than other plant food among food chains to human body. However, little is investigated about the occurrence, fate, and ecological impacts of antibiotics in PV-OVPS. Vegetables are main plant species cultivated in protected facilities in China. Different from PVPS, protected vegetable production systems are characterized by repeated fertilization and irrigation, elongated intensive cultivation period, strengthened environmental factors

(high temperature, high humidity), and frequent disturbance of soil, which certainly affect the physicochemical and biochemical processes of antibiotics in soils. It is speculated that discharge amount of poultry and animal feces will reach 4.5 billion tons in China (Li et al. 2009a). In China, near 80% animal dejecta were utilized without comprehensive harmless disposal. Antibiotics are used in animal livestock production for therapeutic treatment of disease and at subtherapeutic levels for growth promotion and improvement of feed efficiency and their well-being (Boxall et al. 2003). Limited information regarding the fates and ecological impacts in protected and organic soil–vegetable systems was obtained, especially long-term monitoring data.

6.3 Strategies of lowering the introduction and ecological impacts of antibiotics in agro-ecosystems

6.3.1 Controlling the use of antibiotics as feed additives and human medicines to reduce excretion rate

Currently, in order to minimize the occurrence of ecological problems and public health impacts caused by antibiotic contamination in agro-ecosystems, control methods of decreasing antibiotic commercial use, environmental release, and agro-input should be developed. First, the use of antibiotics in livestock farming should be reduced or limited compulsively to lower the agro-input from manures; second, relevant regulations with respect to human use of antibiotics should be issued to avoid the misuse in practices and over-release from biosolids and wastewater.

6.3.2 Developing pretreatment technology to decrease the quantity of antibiotics in organic fertilizer and irrigation water

Antibiotics-contained animal slurry or dejecta applied into farmlands as organic fertilizer without proper harmless pretreatments are the main source of antibiotics contribution to agro-ecosystems (Bagner et al. 2000). Anyway, to decrease the concentration of antibiotics in organic fertilizer and irrigation water is the first step to control the agro-input. Effective pretreatment methods, such as composting and anaerobic fermentation, wastewater treatment technology, must be further developed and optimized. In order to reduce the entrance of antibiotics by fertilization and irrigation ways, some standards of limits of antibiotics concentration in organic fertilizer and irrigation water need to be developed.

6.3.3 Clarifying fates and rhizosphere dynamics of antibiotics in agro-ecosystems

Several studies have been conducted to investigate the contamination status and impacts of antibiotics in protected

soils on vegetable yield and quality (Zhao 2007; Wang and Han 2008; Li et al. 2008; Liu et al. 2009a) and organic agriculture (Hu et al. 2010). However, the behaviors of antibiotics between soil–root interfaces are little understood. In order to reduce the ecological risks, some biological mechanisms should be developed to accelerate the removal processes. Therefore, future extensive works should be focus on the investigations of fates and ecological risks of antibiotics in agro-ecosystems, particularly rhizosphere dynamics and the transfer from soil to crops.

7 Concluding remarks

Numerous studies dealing with antibiotic contamination of effluents of sewage treatment plants, surface water, groundwater, slurry or manures, soils, and sediments have been reported. Consequently, introduction of antibiotics into farmlands has given rise to a growing public concern over the ecological effects of antibiotics in agro-ecosystems. Besides deleterious effects on soil microflora and crop growth, antibiotics can provoke resistant pathogens through long-time exposure due to genetic variation and transfer. As novel persistent pollutants, antibiotics were included in limitations issued by the Food and Agriculture Organization (FAO) and the USA. However, there are no regulations involving antibiotics dealing with quality standards of produce in China. Although the acceptable daily intake values (less than 50 µg/kg) and the maximum residue levels for animal tissues (below 1 mg/kg) have been established (JECFA 2006) by FAO and the World Health Organization, limits have not been established for concentration of agricultural organic fertilizers and plant-based products, e.g., vegetables (Dolliver et al. 2007). Antibiotic ecotoxicological relevance is scarcely known and understood (Rooklidge 2004). Case-by-case studies in terms of species of antibiotics, plants, and soil use patterns are needed to investigate the ecotoxicological potential and their mechanisms of antibiotics in agro-ecosystems (Kotzerke et al. 2011), including source, exposure, and fate evaluation of soil antibiotics, impact investigations on plant and soil ecosystems, crop uptake, and transportation analysis via food chain in all kinds of agro-ecosystems. More importantly, some key issues should be revealed urgently, i.e., (1) crop rhizospheric impacts of antibiotics on soil microorganisms and relevant biochemical processes, particularly beneficial microorganisms (e.g., arbuscular mycorrhizal fungi, rhizobium etc.); (2) uptake of antibiotics via crop uptake, particularly leafy vegetables; (3) risk assessment of metabolites of antibiotics equivalent to their parental compounds in soil–crop systems for they usually being omitted in previous reports; (4) environmental assessment through leaching and runoff;

and (5) fate and ecotoxicity of antibiotics in PV-OVPS. To sum up, further investigation is needed to fully understand the occurrence, fates in agro-ecosystems, particularly in PV-OVPS.

Acknowledgment This work was supported by the project of research and development program for China's sustainable agriculture (II), 2009–2014. I also want to thank three anonymous reviewers for their helpful comments and suggestions and Dr. Zhiping Zhu for providing some pictures.
