Abstract:
We tackle the makespan minimization coupled-tasks problem in presence of compatibility constraints. In particular, we focus on stretched coupled-tasks, i.e. coupled-tasks having the same sub-tasks execution time and idle time duration. We study several problems in frame works of classic complexity and approximation for which the compatibility graph $G_c$ is bipartite (star, chain, ...). In such context, we design some efficient polynomial-time approximation algorithms according to difference parameters of the scheduling problem. When $G_c$ is a $k$-stage bipartite graph, we propose, among other, a $\frac{7}{6}$-approximation algorithm when $k = 1$, and a $\frac{13}{9}$ approximation algorithm when $k = 2$.

keyword: coupled-tasks, scheduling, complexity, approximation algorithm, compatibility graph

Résumé :
Nous nous intéressons au problème de minimiser le temps d’ordonnancement d’un ensemble de tâches couplées en présence de contraintes de compatibilité. En particulier, nous étudions les tâches couplées étirées et montrons que le problème est difficile même lorsque le graphe $G_c$ modélisant les contraintes de compatibilité est une étoile. Nous concentrons notre étude lorsque $G_c$ est un graphe biparti $k$-étapes, et proposons plusieurs résultats d’approximation, notamment un algorithme $\frac{7}{6}$-approché lorsque $k = 1$, et $\frac{13}{9}$-approché pour $k = 2$.

mot-clés: tâches couplées, ordonnancement, complexité, algorithmes d’approximation, graphe de compatibilité
1 Introduction

The detection of an object by a radar system generally uses the following process: a transmitter emits a pulse in some direction which propagates through the environmental medium. If the pulse encounters an object, it is reflected back to the transmitter. Using the transmit time and the direction of the pulse, the transmitter can compute the position of the object. Formally this process is divided into three parts: (1) a first operation of duration $a$ a sensor emits the pulse; (2) then the system waits for a fixed amount of time $L$ the propagation of the pulse and its potential reflexion; (3) then in a second operation of duration $b$ the sensor listen to any pulse echo to conclude of the presence or not of an object and compute its position. Due to the nature of the application, the system works in a non-preemptive mode. Varying the values of parameters $a$, $b$ and $L$ allows, among others, to adapt the detection range. On mono-processor systems, the idle processing time $L$ can be reused to perform other operations, i.e. to schedule another object detection process using another sensor.

Scheduling issues appear when several sensors using different frequencies can work in parallel, while acquisitions using the same frequency have to be delayed in order to avoid interferences. Two acquisition processes $i$ and $j$ are said compatible if they can work in parallel.

We consider in this paper a mono-processor system using several sensors, some of them using the same frequencies. Given a set of data acquisitions with they duration and the list of compatible acquisitions, finding a optimal schedule which minimizes the makespan is a problem hard to solve in general, even under restricted hypothesis on the values of $a$, $b$, $L$ and/or on the list of compatible acquisitions. We study the variation of the complexity when for any acquisition $i$, the durations of each of its operations and the idle time between them are equal. We propose exact and approximation results according to different hypothesis we made on the list of compatible acquisitions.

This article is organized as follows: first we present the general coupled-task model, a natural way to model such a data acquisition process, and the related work. In the next section we introduce the stretched coupled-tasks model and summarize the contribution of this paper. The computational complexity results are detailed in Section 4, while Section 5 focuses on polynomial-time approximation algorithms with performance guarantee for $NP$-Hard instances.

2 Presentation of coupled-tasks and related work

A natural way to model data acquisition process presented in introduction is to use coupled-tasks, introduced first by Shapiro [11]: each acquisition task is a coupled-task $A_i = (a_i, L_i, b_i)$ composed by two sub-tasks of processing time $a_i$ and $b_i$, respectively dedicated for wave transmission and echo reception. Between these two sub-tasks there is a fixed idle time $L_i$ which represents the spread of the echo in the medium. We work in a non-preemptive mode: once started, a sub-task cannot be stopped and then continued later. A valid schedule implies here that for any task started at $t$, the first sub-task is fully executed between $t$ and $t + a_i$, and the second between $t + a_i + L_i$ and $t + a_i + L_i + b_i$. We note $\mathcal{A} = \{A_1, \ldots, A_n\}$ the collection of coupled-tasks to be scheduled.
Two tasks $A_i$ and $A_j$ are said compatible if they use different wave frequencies; any sub-task of $A_i$ may be executed during the idle time of $A_j$ or reciprocally. A valid schedule implies here that for any tasks $A_i$ and $A_j$, if either the first and/or the second sub-task of $A_i$ is scheduled during the idle time of $A_j$, then $A_i$ and $A_j$ must be two compatible tasks. For clarity we say that $A_i$ and $A_j$ are executed in parallel in such a schedule. The parallel execution of $A_i$ and $A_j$ may exist under to configurations, according to the values of $a_i$, $L_i$, $b_i$, $a_j$, $L_j$, $b_j$. A graph $G = (A, E)$ is used to model such this compatibility, where edges from $E$ link any pair of compatible coupled-tasks.

Due to the combinatory of the parameters of the problem, we use the Graham’s notation scheme $\alpha|\beta|\gamma$ [8] (respectively the machine environment, job characteristic and objective function) to characterize the problems related to coupled-tasks. The job characteristics summarizes the conditions made on the values of $a_i$, $L_i$, $b_i$ (independent between tasks, or equal to a constant), and the shape of the compatibility graph $G$. The coupled-tasks scheduling problems under compatibility constraints has been studied in the framework of classic complexity and approximation (see Table 1 - only main results are retained).

## 3 Stretched coupled-task: model and contribution

### 3.1 Model

This paper focuses on stretched coupled-tasks, i.e. coupled-tasks for what the durations of the first sub-task, the second sub-task and the idle time are equal to a stretch-factor applied to an original task $(a_i, L_i, b_i) = (1, 1, 1)$. Formally, a stretched coupled-task $A_i$ is a task such that $a_i = L_i = b_i = \alpha(A_i)$, where $\alpha(A_i)$ is the stretch factor of the task. In the rest of the paper, coupled-tasks are always stretched coupled-tasks, and noted $A_i$ when we need to refer to the values $a_i$, $b_i$ and $L_i$, or with a single identifier, i.e. $x$, otherwise. In such configuration, for two compatible tasks $A_j$ and $A_j$ to be scheduled in parallel, one of the following conditions must hold:

1. either $\alpha(A_i) = \alpha(A_j)$: then the idle time of one task is fully exploited to schedule a sub-task from the other (i.e. $b_i$ is scheduled during $L_j$, and $a_j$ is scheduled during $L_i$), and the completion of the two tasks is done without idle time.

2. or $3\alpha(A_i) \leq \alpha(A_j)$: then task $A_i$ is fully executed during the idle time $L_j$ of $A_j$. For sake of simplify, we say we pack $A_i$ into $A_j$. 

From this observation, one can derive from the compatibility graph $G = (A, E)$ a directed compatibility graph $G_c = (A, E_c)$ by assigning a direction to each edge $E$ from the task with the lowest stretch factor to the task with the highest one. If two compatible tasks $x$ and $y$ have the same stretch factor, then $E_c$ contains both the arc $(x, y)$ and the arc inverted $(y, x)$. Remark that if for any pair of compatible tasks $x$ and $y$ we have $\alpha(x) \neq \alpha(y)$, then $G_c$ is a directed acyclic graph.

Note that when the job characteristics refer to an undirected topology for the compatibility graph (i.e. star, chain), we consider in fact a graph $G_c$ such that their undirected underlying graph $wuc(G_c)$ correspond to the given class.

Given a valid schedule $\sigma$ and a task $A_i$, we note $\sigma(A_i)$ the date when $A_i$ is being executed, i.e. the first (resp. second) sub-task is executed between $\sigma(A_i)$ and $\sigma(A_i) + a_i$ (resp. between $\sigma(A_i) + a_i + L_i$ and $\sigma(A_i) + a_i + L_i + b_i$). We also denote by $seq(W)$ the sum of the processing time of the tasks in any set $W$:

$$seq(W) = 3 \sum_{x \in W} \alpha(x)$$

Remark that, when $W$ is an independent set for $G_c$, the cost of any optimal schedule is at least $seq(W)$. We note $N_G(v)$ the neighborhood of $v$ in $G$. We note $d_G(v) = |N_G(v)|$ the degree of $v$ in $G$, and $\Delta_G$ the maximum degree of $G$.

As we focus our work on bipartite graphs, we recall that a $k$-stage bipartite graph is a digraph $G = (V_0 \cup \cdots \cup V_k, E_1 \cup \cdots \cup E_k)$ where $V_0, \ldots, V_k$ are disjoint vertex sets, and each arc in $E_i$ is from a vertex in $V_i$ to a vertex in $V_{i+1}$. The vertex of $V_i$ are said to be at rank $i$, and the subgraph $G_i = (V_{i-1} \cup V_i, E_i)$ is called the $i$-th stage of $G$, and we write $G = G_1 + \cdots + G_k$. Note that $G$ is acyclic, and that vertices from $V_0$ are always source in $G$ (nodes only incident to outgoing arcs), while vertices from $V_k$ are sink (nodes only incident to ingoing arcs). For clarity, a 1-stage bipartite graphs may be referred as triplet $(X, Y, E)$.

### 3.2 Contribution

We define the main problem of this study as $1|a_i = L_i = b_i = \alpha(A_i), G_c|C_{max}$, study the variation of the complexity when $G_c$ or $wuc(G_c)$ varies, and propose approximation results for instances hard to solve. The results proved in this article are summarized in Table 2.

### 3.3 Prerequisites

We use in this paper known complexity results on four packing-related problems:

Table 2: Complexity and approximation results.
1. The SUBSET SUM (SS) problem is a known problem in which, given a set $S$ of $n$ positive values and $v \in \mathbb{N}$, one asks if there exists a subset $S' \subseteq S$ such that $\sum_{i \in S'} i = v$. This decision problem is well-known to be $\mathcal{NP}$-complete (see [6]). The optimization version problem is sometimes viewed as a KNAPSACK problem, where each item profits and weights coincide to a value in $S$, the knapsack capacity is $v$, and one tries to find the set of packable items with maximum profit.

2. The MULTIPLE SUBSET SUM (MSS) problem is a variant of well-known BIN PACKING in which a number of identical bins is given and one would like to maximize the overall weight of the items packed in the bins such that the sum of the item weights in every bin does not exceed the bin capacity. The problem is also a special case of the MULTIPLE KNAPSACK problem in which all knapsacks have the same capacities and the item profits and weights coincide. Caprara, and al. [2] proved that MSS admits a $\mathcal{PTAS}$, but does not admit a $\mathcal{FPTAS}$ even for only two knapsacks. They also proposed a $\frac{2}{5}$-approximation algorithm in [3].

3. MULTIPLE SUBSET SUM WITH DIFFERENT KNAPSACK CapacITIES (MSSDC) [1] is an extension of MSS considering different bin capacities. MSSDC also admits a $\mathcal{PTAS}$ [1].

4. As a generalization of MSSDC, MULTIPLE KNAPSACK ASSIGNMENT RESTRICTION (MKAR) problem consists to packs weighted items into non-identical capacity-constrained bins, with the additional constraints that each item can be packed in some bins only. Each item as a profit, the objective here is to maximize the sum of profits of packed items. Considering the profit of each item equals its weight, [4] proposed a $\frac{1}{2}$-approximation.

We also use a known result concerning a variant of the $\mathcal{NP}$-complete problem 3SAT [6], denoted subsequently by ONE-IN-(2,3)SAT(2,1): this problem aim to ask is there exists an assignment of $n$ boolean variables, with $n \mod 3 \equiv 0$, which satisfies a set of $n$ clauses of cardinality 2 and $n/3$ clauses of cardinality 3 such that:

- Each clause of cardinality 2 is equal to $(x \lor \bar{y})$ for some $x, y \in \mathcal{V}$ with $x \neq y$.
- Each of the $n$ literals $x$ (resp. of the literals $\bar{x}$) for $x \in \mathcal{V}$ belongs to one of the $n$ clauses of cardinality 2, thus to only one of them.
- Each of the $n$ (positive) literals $x$ belongs to one of the $n/3$ clauses of cardinality 3, thus to only one of them.
- Whenever $(x \lor \bar{y})$ is a clause of cardinality 2 for some $x, y \in \mathcal{V}$, then $x$ and $y$ belong to different clauses of cardinality 3.

**Question:** Is there a truth assignment $I : \mathcal{V} \to \{0, 1\}$ whereby each clause in $\mathcal{C}$ has exactly one true literal?

**Example:** The following logic formula is a valid instance of ONE-IN-(2,3)SAT(2,1):

$$(x_0 \lor x_1 \lor x_2) \land (x_3 \lor x_4 \lor x_5) \land (\bar{x}_0 \lor x_3) \land (\bar{x}_3 \lor x_0) \land (\bar{x}_4 \lor x_2) \land (\bar{x}_1 \lor x_4) \land (\bar{x}_5 \lor x_1) \land (\bar{x}_2 \lor x_5).$$

The answer to ONE-IN-(2,3)SAT(2,1) is yes. It is sufficient to choose $x_0 = 1$ (1 for true), $x_3 = 1$ and $x_i = 0$ (0 for false) for $i \in \{1,2,4,5\}$. This yields a truth
assignment that satisfies the formula, and there is exactly one true literal for each clause. The proof of the $\mathcal{NP}$-completeness is given in [7].

4 Computational complexity

We present several $\mathcal{NP}$-complete and polynomial results. We first show the problem is $\mathcal{NP}$-hard even when the compatibility graph is a star (Theorem 2), but then show it is solvable with a $O(n^2)$ time complexity algorithm when $G$ is a chain (Theorem 3). Then we focus our analysis when $G_e$ is a 1-stage bipartite graph. We prove the problem is solvable with a $O(n^3)$ polynomial algorithm if $\Delta_G = 2$ (Theorem 4), but becomes $\mathcal{NP}$-hard when $\Delta_G = 3$ (Theorem 5).

**Theorem 1** The problem $1|a_i = L_i = b_i = \alpha(A_i), G = \text{star}|C_{\max}$ is polynomial if the central node admits at least one outgoing arc.

**Proof** If it exists a least one outgoing arc from the central node $x$, then the optimal solution consists in executing the central node in one coupled-task $y$ such that $(x, y) \in G_e$. The remaining tasks are processed sequentially after the completion of the $y$-task. □

**Theorem 2** The problem $1|a_i = L_i = b_i = \alpha(A_i), G = \text{star}|C_{\max}$ is $\mathcal{NP}$-hard if the central node admits only incoming arc.

**Proof** It is easy to see that $1|\alpha(A_i) = a_i = L_i = b_i, G = \text{star}|C_{\max}$ is in $\mathcal{NP}$. We propose a reduction to SS problem. From an instance of SS composed by a set $S$ of $n$ positive values and $v \in \mathbb{N}$ (with $v \geq x, \forall x \in S$), we construct an instance of $1|\text{star}, \alpha_i = a_i = L_i = b_i|C_{\max}$ in the following way:

1. For each value $i \in S$ we introduce a coupled-task $x$ with $\alpha(x) = i$. Let $T$ be the set of these tasks.

2. We add a task $y$ with $\alpha_y = a_y = L_y = b_y = 3v$.

3. We define a compatibility constraint between each task $x \in T$ and $y$.

Clearly the compatibility graph $G$ is a star with $y$ as the central node. The transformation is clearly polynomial. It easy to see that $1|\alpha(A_i) = a_i = L_i = b_i, G = \text{star}|C_{\max}$ is $\mathcal{NP}$-hard as following:

- Considering the characteristics of the instance when $G_e$ is a star, any (optimal) valid scheduling consists in scheduling sequentially a subset $T' \subseteq T$ of task during the idle time of $y$, and in scheduling after this the other tasks from $T$ sequentially. Then the optimal schedule would consist in maximizing $w = 3 \sum_{t \in T'} \alpha_t$ under the constraint $w \leq L_y$, and in producing a schedule with a total length equal to the time to schedule $y$ (i.e. $3\alpha_y$) plus the time to schedule tasks not executed during $L_y$ the idle time of $y$ (i.e. $3 \sum_{t \notin T'} \alpha_t$); in other words a schedule of time $3\alpha_y + 3 \sum_{t \in T} \alpha_t - 3 \sum_{t \in T} \alpha_t$.

If one can find an optimal schedule of length $3 \sum_{t \in T} \alpha_t + 2\alpha_y$, then one can exhibit a subset $T^* \subseteq T$ with $3 \sum_{t \in T^*} \alpha_t = L_y = 3v$ and by construction one can deduce a solution to ssby taking $S^* = \{ \cup \alpha_x| x \in T^* \}$.  

7
• Conversely, if one can exhibit a subset $S^* \subseteq S$ thus that $\sum_{i \in S^*} i = v$, then one can produce an optimal schedule by executing sequentially tasks $x$ with $\alpha_x = i$, where $i \in S^*$, during the idle time $L_y = 3v$ of task $y$, and by executing sequentially tasks $z \in S\setminus S^*$ immediately after the execution of $y$.

Theorem 3 The problem $1|a_i = L_i = b_i = \alpha(A_i), G = \text{chain}|C_{\text{max}}$ admits a polynomial-time algorithm.

Proof When the compatibility graph is a chain, compatibility constraints require tasks to be executed either alone, by pair only, or two consecutively tasks in another big one. The last case occurs only when a vertex $x$ of degree two, called peak, has its two neighbor $y$ and $z$ which can be entirely executed in the inactivity time of $x$. Thus if $3\alpha_y + 3\alpha_z \leq \alpha_x$, then one can execute $y$ and $z$ during the idle time of $x$; The schedule length for this block is exactly $3\alpha_x$. We can observe that the peaks can not be executed in another tasks. Therefore, w.l.o.g. we can assume that there exists an optimal solution where the peak tasks and their neighbors are executed together.

From this result, we can in polynomial time modify $G$ in $G_m$ where all peak vertices, their neighbors and the associated edges are removed. Thus $G_m$ is a collection of chains and the best scheduling associated to this graph requires tasks to be executed either alone or by pair.

Given $x$ and $y$ two compatibles tasks, only the two following configurations allow them to be scheduled pairwise (by blocks):

1. if $\alpha_x = \alpha_y$, then one can execute $a_y$ during the idle time of $x$ and $b_x$ during the idle time of $y$. The makespan for this block is exactly $4\alpha_x$.

2. if $\alpha_x \leq \frac{\alpha_y}{3}$, then one can execute entirely $x$ during the idle time of $y$, the makespan for this block is exactly $3\alpha_y$, including an inactivity period of $\alpha_y - 2\alpha_x$.

By weighting each edge of the graph $G_m$ with the sequential time of the overlap of the two tasks which form the edge, our problem has a solution if we find a matching that minimizes the weight of the matching edges and the isolated vertices.

This problem can be solved in a polynomial-time by reducing the problem to the search for a minimum weighted perfect matching. This problem can be polynomially solved in $O(n^2m)$ time complexity [5]. In order to obtain a graph with even number of vertices and such that finding a perfect matching is possible, we construct a graph $H_c = (V_H, E_H, w)$ and define a weighted function $w : E \rightarrow \mathbb{N}$ as follows:

1. Let $I_1$ be an instance of our problem with a compatibility graph $G_m = (V_m, E_m)$, and $I_2$ an instance of the minimum weight perfect matching problem in graph constructed from $I_1$. We consider a graph $H_c$, consisting of two copies of $G_m$, denoted $G'_m = (V'_m, E'_m)$ and $G''_m = (V''_m, E''_m)$. The vertex corresponding to $x \in V_m$ is denoted $x'$ in $G'_m$ and $x''$ in $G''_m$. Moreover, $\forall i = 1, \ldots, n$, an edge $\{x', x''\}$ in $E_{Hc}$ is added and we state $w(\{x', x''\}) = 3\alpha_x$. This weight represents the sequential time of the task alone $x'$. We have $H_c = G'_m \cup G''_m = (V_m \cup V''_m, E_m \cup E''_m)$, with $|V_m \cup V''_m|$ of even size.

2. For two compatibles tasks $x'$ and $y'$ with $3\alpha_{x'} \leq \alpha_{y'}$ or $3\alpha_{y'} \leq \alpha_{x'}$, we add the edges $\{x', y'\}$ and $\{x'', y''\}$ in $E$ and we state $w(\{x', y'\}) = w(\{x'', y''\}) = \frac{3 \times \max\{\alpha_{x'}, \alpha_{y'}\}}{2}$. 

3. For two compatibles tasks $x'$ and $y'$ with $\alpha_{x'} = \alpha_{y'}$, we add the edges \{$x', y'$\} and \{$x'', y''$\} in $E$, and we state $w(\{x', y'\}) = w(\{x'', y''\}) = \frac{4x\alpha_{x'}}{2}$.

In order to provide a polynomial-time algorithm solving our problem, we will prove firstly the following proposition.

**Proposition 1** For a minimum weight perfect matching $C$, we can associate a schedule of minimum processing times $C$ and vice versa.

![Figure 1: Example of the transformation](image)

**Proof**

By construction $H_C$ contains an even number of vertices, and the fact that each vertex of $G'_c$ is connected to an equivalent vertex in $G''_c$, finding a perfect matching on the graph $H_C$ is possible. This means that there exists a schedule such that each task is executed only once time. Note that the matching in $G'_c$ is not necessarily identical to the one in $G''_c$, but they still have the same weight. The makespan obtained is equal to the sum of the processing times of the obtained blocks and those of isolated tasks. And since each block has an execution time equal to the weight of the equivalent edge in the perfect matching, we have the sum of edges weights of the matching which is equal to the blocks sum of the scheduling obtained.

Thus, for a minimum weight perfect matching $C$, we can associate a schedule of minimum length $C$ and vice versa. This ends the proof of the Proposition 1.

**Proof continuation of Theorem 3**

The proposition 1 shows the relationship between a solution to our problem with $G_m$ and a solution of a minimum weight perfect matching in $H_C$. However, the Edmonds algorithm can find a minimum weight perfect matching in $O(n^2m)$ [5]. So the optimization problem with $G_m$ is polynomial, and if one adds the execution of the blocks created by removed vertices, this leads to the problem 1\{a_i = L_i = b_i = \alpha(A_i), G = chain\}|C_{max} is polynomial.

In following, we study the variation of the complexity in the case of the compatibility graph is oriented in presence of a 1-stage bipartite graph according to the different values.

**Theorem 4** The problem of deciding whether an instance of 1\{a_i = L_i = b_i = \alpha(A_i), G_c = t-stage bipartite, \Delta G_c = 2\}|C_{max} is polynomial.

**Proof** Let $G_c = (X, Y, E)$ be a 1-stage bipartite compatibility graph. Y-tasks will always be scheduled sequentially. The aim is to fill their idle time with a maximum
Theorem 5 The problem of deciding whether an instance of 1|\(a_i = L_i = b_i = \alpha(A_i), G_c = 1\)-stage bipartite, \(\Delta_{G_c} = 3|C_{\max}\) has a schedule of length at most 54 has \(\mathcal{NP}\)-complete with \(n\) the number of tasks.

Proof It is easy to see that 1|\(a_i = L_i = b_i = \alpha(A_i), G_c = 1\)-stage bipartite, \(\Delta_{G_c} = 3|C_{\max} = 54\in \mathcal{NP}\). Our proof is based on a reduction from ONE-IN-(2,3)SAT(2,1): given a set \(V\) of \(n\) boolean variables with \(n\) mod 3 \(\equiv 0\), a set of \(n\) clauses of cardinity two and \(n/3\) clauses of cardinity three, we construct an instance \(\pi\) of the problem 1|\(a_i = L_i = b_i = \alpha(A_i), G_c = 1\)-stage bipartite, \(\Delta_{G_c} = 3|C_{\max} = 54\) in following way (Figure 2 illustrates the construction):

1. For all \(x \in V\), we introduce four variable-tasks: \(x, x', \bar{x}\) and \(\bar{x}'\) with \((a_i, L_i, b_i) = (1,1,1), \forall i \in \{x, x', \bar{x}, \bar{x}'\}\). This variable-tasks set is noted \(V_T\).
2. For all \(x \in V\), we introduce three literal-tasks \(L_x, C^x\) and \(\bar{C}^x\) with \(L_x = (2,2,2); C^x = \bar{C}^x = (6,6,6)\). The set of literal-tasks is denoted \(L_T\).
3. For all clauses with a length of three, we introduce two clause-tasks \(C_i\) and \(\bar{C}_i\) with \(C^i = (3,3,3)\) and \(\bar{C}^i = (6,6,6)\).
4. For all clauses with a length of two, we introduce one clause-task \(C^i\) with \(C^i = (3,3,3)\). The set of clause-tasks is denoted \(C_T\).
5. The following arcs model the compatibility constraints:
   a. For all boolean variables \(x \in V\), we add the arcs \((L_x, C^x)\) and \((L_x, \bar{C}^x)\)
   b. For all clauses with a length of three denoted \(C_i = (y \lor z \lor t)\), we add the arcs \((y, C^i), (z, C^i), (t, C^i)\) and \((\bar{y}, \bar{C}^i), (\bar{z}, \bar{C}^i), (\bar{t}, \bar{C}^i)\).
   c. For all clauses with a length of two denoted \(C_i = (x \lor \bar{y})\), we add the arcs \((x', C^i)\) and \((\bar{y}, C^i)\).
   d. Finally, we add the arcs \((x, C^x), (x', C^x)\) and \((x, \bar{C}^x)\) and \((x', \bar{C}^x)\).
This transformation can be computed clearly in polynomial time. The proposed compatibility graph is 1-stage bipartite and $d_{G_c}(x) \leq 3$, $\forall x \in V_T \cup L_T \cup C_T$.

In follows, we say that a task $x$ is merged to a task $y$, if $x$ is a compatibility constraint from $x$ to $y$; i.e. the coupled-task $x$ may be executed during the idle of coupled-task $y$.

- Let us first assume that there is a schedule with length of $54n$ at most. We prove that there is a truth assignment $I : V \rightarrow \{0, 1\}$ such that each clause in $C$ has exactly one true literal (i.e. one literal equal to 1). We make some essentials remarks:

1. The length of the schedule is given by an execution time of the coupled-tasks admitting only incoming arcs, and the value is $54n = 3\alpha_{CT}[CT] + \alpha_{LT}(\alpha_{LT} - |\{L_x, x \in V\}|) = 9(|C^i \in CT| of length 2 and 3| + 18|\{C^i \in CT| + 18|\{C^x and \bar{C}^x \in LT|] = 9 \times \frac{n}{3} + 18 \times \frac{2n}{3} + 18 \times 2n$.

   Thus, all tasks from $V_T \cup \{L_x, x \in V\}$ must be merged with tasks from $CT \cup (LT - \{L_x, x \in V\})$.

2. By the construction, at most three tasks can be merged together.

3. $L_x$ is merged with $C^x$ or $\bar{C}^x$.

4. The allocation of coupled-tasks from $CT \cup (LT - \{L_x, x \in V\})$ leads to $18n$ idle time. The length of the variable-tasks $V_T$ and $L_x$ equals $18n$ (in these coupled-tasks there are $6n$ idle times).

5. If the variable-tasks $x$ and $x'$ are not merged simultaneously with $C^x$, i.e. only one of these tasks is merged with $C^x$, so, by with the previous discussion, it is necessary to merge a literal-task $L_y$, with $x \neq y$ one variable-task ($\bar{y}$ or $\bar{y}$') with $C^y$ or $\bar{C}^y$. It is impossible by size of coupled-tasks. In
the same ways, the variable-tasks \( \bar{x} \) et \( \bar{x}' \) are merged simultaneously with \( C^x \).

6. Hence, first \( x \) and \( x' \) are merged with \( C^x \) or with clause-task where the variable \( x \) occurs. Second, \( \bar{x} \) and \( \bar{x}' \) are merged with \( \bar{C}^x \) or a clause-task.

So, we affect the value "true" to the variable \( l \) iff the variable-task \( l \) is merged with clause-task(s) corresponding to the clause where the variable \( l \) occurs. It is obvious to see that in the clause of length three and two we have one and only one literal equal to "true".

• Conversely, we suppose that there is a truth assignment \( I : V \rightarrow \{0, 1\} \), such that each clause in \( C \) has exactly one true literal.

- If the variable \( x = true \) then we merged the vertices \( L_x \) with \( C^x \); \( x \) with the clause-task \( C^x \) corresponding to the clause of length three which \( x \) occurs; \( x' \) with the clause-task \( C^x \) corresponding to the clause of length two which \( x \) occurs; and \( \bar{x}, \bar{x}' \) with \( \bar{C}^x \).

- If the variable \( x = false \) then we merged the vertices \( L_x \) with \( \bar{C}^x \); \( \bar{x} \) with the clause-task corresponding to the clause of length two which \( \bar{x} \) occurs; \( \bar{x}' \) with the clause-task \( \bar{C}^i \) corresponding to the clause \( (C) \) of length three which \( x \) occurs; and \( x, x' \) with \( C^x \).

For a feasible schedule, it is sufficient to merge vertices which are in the same partition. Thus, the length of the schedule is at most \( 54n \).

\[ \square \]

5 Polynomial-time approximation algorithms

5.1 Star graph

Theorem 6 The problem \( 1|a_i = L_i = b_i = \alpha(A_i), G = star|C_{max} \) admits a \( FPTAS \).

Proof The central node admits only incoming arcs (the case of the central node admits at least one outgoing arc is given by Corollary 1). Therefore, we may use the solution given by the subset sum (SS) (see [9] and [10]). Indeed, the schedule is follows: the central node is executed first with the coupled-tasks chosen by an \( FPTAS \) algorithm, the remaining tasks are processed after the completion of the central node.

\[ \square \]

5.2 1–stage bipartite graph

Scheduling coupled-tasks during the idle time of others can be related to packing problems, especially when the constraint graph \( G_c \) is a bipartite graph. In the following, we propose several approximation when \( G_c \) is a 1–stage bipartite graph.

Lemma 1 Let \( \mathcal{P} \) be a problem with \( \mathcal{P} \in \{MKAR, MSSDC, MSS\} \) such that \( \mathcal{P} \) admits a \( \rho \)-approximable then the following problems
1. $|a_i| = L_i = b_i = \alpha(A_i), G_c = 1$-stage bipartite $|C_{max}|$

2. $|a_i| = a_i = L_i = b_i$, complete bipartite $|C_{max}|$

3. $|a_i| = a_i = L_i = b_i$, complete bipartite $|C_{max}|$ where the constraint graph is a complete bipartite $G=(X,Y)$, and all the tasks from $Y$ have the same $\alpha(y)$.

is approximable to a factor $1 + \frac{(1-p)}{3}$.

**Proof**

1. Let consider an instance of $1|\alpha_i = a_i = L_i = b_i, G_c = 1$-stage bipartite $|C_{max}|$ such that $G_c = (X, Y, E)$, where $X \cup Y$ are coupled-tasks, and by a stretch factor function $\alpha : X \cup Y \rightarrow \mathbb{N}$, and arcs from $E$ model the constraints between tasks.

   In such instance, any valid schedule consists to find for each task $y \in Y$ a subset of compatible tasks $X_y \subseteq X$ to pack into $y \in Y$, each task of $x$ being packed at most once. Let $X_p = \bigcup_{y \in Y} X_y$ be the union of tasks of $X$ packed into a task from $Y$. Let $X_p$ the set of remaining tasks, with $X_p = X / X_p$. Obviously, we have:

   $$seq(X_p) + seq(X_p) = seq(X) \quad (1)$$

As $Y$ is an independent set in $G$, tasks from $Y$ have to be scheduled sequentially in any (optimal) solution. The length of any schedule $S$ is then the time to execute entirely tasks from $Y$ plus the length to schedule sequentially the tasks from $X_p$. Formally:

   $$C_{max}(S) = seq(Y) + seq(X_p) \quad (2)$$

From Eq. (1) and (2) we have:

   $$C_{max}(S) = seq(Y) + seq(X) - seq(X_p). \quad (3)$$

We use here a reduction to MKAR: each task $x$ from $X$ is an item having a weight $3.\alpha(x)$, each task from $Y$ is a bin with capacity $\alpha(y)$, and each item $x$ can be packed on $y$ if and only if the edge $\{x, y\}$ belong to the bipartite graph.

Using algorithms and results from the literature, one can obtain an assignment of some items into bins, and note $X_p$ the set of packed items. The cost of the solution for the MKAR problem is $seq(X_p)$. If MKAR is approximable to a factor $\rho$, then we have:

   $$seq(X_p) \geq \rho \times seq(X_p^*), \quad (4)$$

where $X_p^*$ is the set of packable items with the maximum profit. Combining Eq. (3) and (4), we obtain a solution for $1|\alpha_i = a_i = L_i = b_i, bipartite|C_{max}$ with a length:

   $$C_{max}(S) \leq seq(Y) + seq(X) - \rho \times seq(X_p^*) \quad (5)$$

As $X$ and $Y$ are two fixed sets, a optimal solution $S^*$ with minimal length $C_{max}(S^*)$ is obtained when $seq(X_p)$ is maximum, i.e. when $X_p = X_p$. The length of any optimal solution is here:

   $$C_{max}(S^*) = seq(Y) + seq(X) - seq(X_p^*) \quad (6)$$
Using Eq. (5) and (6), the ratio obtained between our solution $S$ and the optimal one $S^*$ is:

$$\frac{C_{\text{max}}(S)}{C_{\text{max}}(S^*)} \leq \frac{\text{seq}(Y) + \text{seq}(X) - \rho \times \text{seq}(X^*)}{\text{seq}(Y) + \text{seq}(X) - \text{seq}(X^*)} \leq 1 + \frac{(1 - \rho) \times \text{seq}(X^*)}{\text{seq}(Y) + \text{seq}(X) - \text{seq}(X^*)}$$

(7)

By definition, $X^*_p \subseteq X$. Moreover, as the processing time of $X^*_p$ cannot exceed the idle time of tasks from $Y$, we obtain:

$$\text{seq}(X^*_p) \leq \frac{1}{3} \text{seq}(Y)$$

(8)

Combined to Eq. (7), we obtain the following upper bound:

$$\frac{C_{\text{max}}(S)}{C_{\text{max}}(S^*)} \leq 1 + \frac{(1 - \rho)}{3}.$$

(9)

We obtain the desired result.

2. For the problem $1|\alpha_i = a_i = L_i = b_i; \text{complete bipartite}|C_{\text{max}}$, the proof is identical keeping in mind that MSSDC is a special case of MKAR where each item can be packed in any bin.

3. For the problem $1|\alpha_i = a_i = L_i = b_i; \text{complete bipartite}|C_{\text{max}}$ where the constraint graph is a complete bipartite $G = (X, Y)$, and all the tasks from $Y$ have the same $\alpha(y)$, the proof is identical as previously since MSSDC is a generalization of MSS.

\[\square\]

**Theorem 7** The following problems admits a polynomial-time approximation algorithms:

1. The problem $1|\alpha_i = L_i = b_i = \alpha(A_i), G_c = 1$-stage bipartite|$C_{\text{max}}$ is approximable to a factor $\frac{7}{6}$.

2. The problem $1|\alpha_i = L_i = b_i = \alpha(A_i), G_c = \text{complete} 1$-stage bipartite|$C_{\text{max}}$ admits a $PTAS$.

3. The problem $1|\alpha_i = L_i = b_i = \alpha(A_i), G_c = \text{complete} 1$-stage bipartite|$C_{\text{max}}$, where all the tasks from $Y$ have the same stretch factor $\alpha(y)$:
   
   (a) is approximable to a factor $\frac{14}{12}$.
   
   (b) admits a $PTAS$.

**Proof**

1. Authors from [4] proposed a $\rho = \frac{1}{2}$—approximation algorithm for MKAR. Reusing this result with Lemma 1, we obtain a $\frac{7}{6}$—approximation for $1|\alpha_i = L_i = b_i = \alpha(A_i), G_c = 1$-stage bipartite|$C_{\text{max}}$.

2. We know that MSSDC admits a $PTAS$ [1], i.e. $\rho = 1 - \epsilon$. Using this algorithm to compute such a $PTAS$ and Lemma 1, we obtain an approximation ratio of $1 + \frac{1}{3}$ for this problem.
3. The problem $1|a_i = L_i = b_i = \alpha(A_i), G_c = \text{complete 1-stage bipartite}|C_{\text{max}}$, where all the tasks from $Y$ have the same stretch factor $\alpha(y)$:

(a) Authors from [3] proposed a $\rho = \frac{3}{4}$-approximation algorithm for MSS. Reusing this result with Lemma 1, we obtain a $\frac{13}{12}$-approximation for $1|\alpha_i = a_i = L_i = b_i, \text{complete bipartite}|C_{\text{max}}$.

(b) They also proved that MSS admits a $\mathcal{PTAS}$ [2], i.e. $\rho = 1 - \epsilon$. Using the algorithm to compute such a $\mathcal{PTAS}$ and Lemma 1, we obtain an approximation ratio of $1 + \frac{\epsilon}{5}$ for $1|\alpha_i = L_i = b_i = \alpha(A_i), G_c = \text{complete 1-stage bipartite}|C_{\text{max}}$ when nodes from $Y$ have the same stretch factor. □

5.3 2-stage bipartite graph

**Theorem 8** The problem $1|a_i = L_i = b_i = \alpha(A_i), G_c = \text{2-stage bipartite}|C_{\text{max}}$ is approximable to a factor $\frac{13}{9}$.

**Proof** Reusing the notation introduced for k-stage bipartite graph (see Section 5.3), we consider an instance of $1|a_i = L_i = b_i = \alpha(A_i), G_c = \text{2-stage bipartite}|C_{\text{max}}$ where $G_c = (V_0 \cup V_1 \cup V_2; E_1 \cup E_2)$, where each arc in $E_i$ is from a vertex in $V_i$ to a vertex in $V_{i+1}$, for $i \in 1, 2$.

**Definition 1** We note $V_{ip}$ ($p=\text{packed}$), ($\text{resp. } V_{ia}$ ($a=\text{alone}$)) $i = 0, 1$ the set of tasks merged (resp. remaining) in any task from $y \in V_{i+1}$ in a solution $S$. Moreover, $V_{ib}$ ($b=\text{box}$), $i = 1, 2$ the set of tasks scheduled with some tasks from $V_{i-1}$ merged into it. This notation is extended to a optimal solution $S^*$ by adding a star in the involved variables.

Considering the specificities of the instance, in any (optimal) solution we make some essential remarks:

1. Tasks from $V_0$ are source nodes for $G_c$, and can be either scheduled alone, or merged into some tasks from $V_1$ only. Given any solution $S$ to the problem on $G_c$, $\{V_{0p}, V_{0a}\}$ is a partition of $V_0$.

2. Tasks from $V_1$ can be either scheduled alone, merged into some tasks from $V_2$, or scheduled with some tasks from $V_0$ merged into it. Given any solution $S$ to the problem on $G_c$, $\{V_{1p}, V_{1a}, V_{1b}\}$ is a partition of $V_1$.

3. Tasks from $V_2$ form an independent set for $G_c$, and have to be scheduled sequentially in any schedule, either alone, or with some tasks from $V_1$ merged into it. Given any solution $S$ to the problem on $G_c$, $\{V_{2a}, V_{2b}\}$ is a partition of $V_2$.

Any solution would consist to schedule first each task with at least one task merged into it, then to schedule the remaining tasks (alone). Given an optimal solution $S^*$, the length of $S^*$ is given by the following equation:

$$S^* = \text{seq}(V_{1b}) + \text{seq}(V_{2b}) + \text{seq}(V_{0a}) + \text{seq}(V_{1a}^*) + \text{seq}(V_{2a}^*)$$  \hfill (10)
or, more simply
\[ S^* = seq(V_2) + seq(V_{1b}^*) + seq(V_{0a}^*) + seq(V_{1a}^*) \] (11)

Note that \( V_{0p}^* \) and \( V_{1a}^* \) are not part of the equation, as they are scheduled during the idle time of \( V_{1b}^* \) and \( V_{2d}^* \).

The main idea of the algorithm is divided into three parts:

1. First we compute a part of the solution with a \( \frac{7}{6} \)-approximation on \( G_0 \) thanks to Theorem 7, where \( G_0 = G_c[V_0 \cup V_1] \) is the 1-th stage of \( G_c \).

2. Then we compute a second part of the solution with a \( \frac{7}{6} \)-approximation on \( G_1 \) thanks to Theorem 7, where \( G_1 = G_c[V_1 \cup V_2] \) is the 2-th stage of \( G_c \).

3. To finish we merge these two parts and resolve potential conflicts between them.

Let consider an instance restricted to the graph \( G_0 \). Note that \( G_0 \) is a 1-stage bipartite graph. Let \( S^*[G_0] \) be an optimal solution on \( G_0 \). Let us note \( V_{0p}^*[G_0] \) the set of tasks from \( V_0 \) packed into tasks from \( V_1 \) in \( S^*[G_0] \), and \( V_{0a}^*[G_0] \) the set of remaining tasks.

Obviously, we have:
\[ S^*[G_0] = seq(V_1) + seq(V_{0a}^*[G_0]) \] (12)

Given any solution \( S[G_0] \), let us note \( V_{1b}[G_0] \) the set of tasks from \( V_1 \) with at least one task from \( V_0 \) merged into them, and \( V_{1a}[G_0] \) the remaining tasks. Let us note \( V_{0p}[G_0] \) the set of tasks from \( V_0 \) merged into \( V_1 \), and \( V_{0a}[G_0] \) the set of remaining tasks. We use Theorem 7, Lemma 1, and the demonstration presented in their proof from [4], to compute a solution \( S[G_0] \) such that:
\[ seq(V_{0p}[G_0]) \geq \frac{1}{2} seq(V_{0p}^*[G_0]) \] (13)

Note that we have
\[ seq(V_{0p}[G_0]) + seq(V_{0a}[G_0]) = seq(V_{0p}^*[G_0]) + seq(V_{0a}^*[G_0]) = seq(V_0) \] (14)

As \( V_{0a}^*[G_0] \) represents the set of tasks not packed into \( V_1 \) in an optimal \( S^*[G_0] \) such that \( seq(V_{0a}^*[G_0]) \) is minimal, we know that \( seq(V_{0a}^*[G_0]) \leq seq(V_{0a}^*) \). Combining Equation (13) and Equation (14), one obtain:
\[ seq(V_{0a}[G_0]) \leq seq(V_{0a}^*[G_0]) + \frac{1}{2} seq(V_{0p}^*[G_0]) \leq seq(V_{0a}^*) + \frac{1}{2} seq(V_{0p}^*[G_0]) \] (15)

We use an analog reasoning on an instance restricted to the graph \( G_1 \). Let \( S^*[G_1] \) be an optimal solution on \( G_1 \). Let us note \( V_{1p}^*[G_1] \) the set of tasks from \( V_1 \) packed into tasks from \( V_2 \) in \( S^*[G_1] \), and \( V_{1a}^*[G_1] \) the set of remaining tasks. Given any solution \( S[G_1] \), let us note \( V_{2a}[G_1] \) the set of tasks from \( V_2 \) with at least one task from \( V_1 \) merged into them, and \( V_{1a}[G_1] \) the remaining tasks. One can compute a solution \( S[G_1] \) based on a set of tasks \( V_{1p}[G_1] \) packed in \( V_2 \) such that:
\[ seq(V_{1p}[G_1]) \geq \frac{1}{2} seq(V_{1p}^*[G_1]) \] (16)
\[
\text{seq}(V_{1a}[G_1]) \leq \text{seq}(V_{1a}^*[G_1]) + 1/2 \text{seq}(V_{1p}^*[G_1]) \leq \text{seq}(V_{1a}) + 1/2 \text{seq}(V_{1p}^*[G_1])
\]  \hspace{1cm} (17)

as we know that \(\text{seq}(V_{1a}^*[G_1]) \leq \text{seq}(V_{1a})\).

We design the feasible solution \(S\) for \(G_c\) as follows:

- We compute a solution \(S[G_1]\) on \(G_1\), then we add to \(S\) each task from \(V_2\) and the tasks from \(V_1\) merged into them (i.e. \(V_{1p}[G_1]\)) in \(S[G_1]\).
- Then we compute a solution \(S[G_0]\) on \(G_0\), then we add to \(S\) each task \(v\) from \(V_{1b}[G_0]/V_{1p}[G_1]\) and the tasks from \(V_0\) merged into them.
- The tasks \(V_{1a}[G_1]/V_{1b}[G_0]\) and \(V_{0a}[G_0]\) are added to \(S\) and scheduled sequentially.
- We note \(V_{\text{conflict}}\) the set of remaining tasks, i.e. the set of tasks from \(V_0\) which are merged into a task \(v \in V_1\) in \(S[G_0]\), thus that \(v\) is merged into a task from \(V_2\) in \(S[G_1]\).

Remark that:

\[
\text{seq}(V_{1b}[G_0]/V_{1p}[G_1]) + \text{seq}(V_{1a}[G_1]/V_{1b}[G_0]) = V_{1a}(G_1)
\]  \hspace{1cm} (18)

Thus the cost of our solution \(S\) is

\[
S = \text{seq}(V_2) + \text{seq}(V_{1a}[G_1]) + \text{seq}(V_{0a}[G_0]) + \text{seq}(V_{\text{conflict}})
\]  \hspace{1cm} (19)

It is also clear that:

\[
\text{seq}(V_{\text{conflict}}) \leq \frac{1}{3} \text{seq}(V_{1p}[G_1]) \leq \frac{1}{3} \text{seq}(V_{1p}^*[G_1])
\]  \hspace{1cm} (20)

Using Equations (15), (17) and (20) in Equation (19), we obtain

\[
S \leq \text{seq}(V_2) + \text{seq}(V_{1a}^*) + \frac{5}{6} \text{seq}(V_{1p}^*[G_1]) + \text{seq}(V_{0a}^*) + \frac{1}{2} \text{seq}(V_{0p}^*[G_0])
\]  \hspace{1cm} (21)

Using Equations (11) and (21), we obtain

\[
S \leq S^* + \frac{5}{6} \text{seq}(V_{1p}^*[G_1]) + \frac{1}{2} \text{seq}(V_{0p}^*[G_0])
\]  \hspace{1cm} (22)

We know that \(S^* \geq \text{seq}(V_2)\). We also know that tasks from \((V_{1p}^*[G_1])\) must be merged into tasks from \(V_2\) and cannot exceed the idle time of \(V_2\), implying that \(\text{seq}(V_{1p}^*[G_1]) \leq \frac{1}{3} \text{seq}(V_2)\). One can write the following:

\[
\frac{\frac{5}{6} \text{seq}(V_{1p}^*[G_1])}{S^*} \leq \frac{\frac{5}{6} \times \frac{1}{3} \text{seq}(V_2)}{\text{seq}(V_2)} \leq \frac{5}{18}
\]  \hspace{1cm} (23)

We know that tasks from \((V_{0p}^*[G_0])\) must be merged into tasks from \(V_1\) and cannot exceed the idle time of \(V_1\), implying that \(\text{seq}(V_{0p}^*[G_0]) \leq \frac{1}{3} \text{seq}(V_1)\). We also know that \(S^* \geq \text{seq}(V_1)\), as \(V_1\) is an independent set of \(G_c\). One can write the following:

\[
\frac{\frac{1}{2} \text{seq}(V_{0p}^*[G_0])}{S^*} \leq \frac{\frac{1}{2} \times \frac{1}{3} \text{seq}(V_1)}{\text{seq}(V_1)} \leq \frac{1}{6}
\]  \hspace{1cm} (24)
Finally, with Equations (22), (23) and (24) the proof is finished:

$$\frac{S}{S^*} \leq \frac{13}{9}$$

(25)

6 Conclusion

The results proposed in this paper are summarized in Table 2. New presented results suggest the main problem of coupled tasks scheduling remains difficult even for restrictive instances, here stretched coupled-tasks when the constraint graph is a bipartite graph. When we consider stretched coupled-tasks, the maximum degree $\Delta_G$ seems to play an important role on the problem complexity, as the problem is already $\mathcal{NP}$-Hard to solve when the constraint graph is a star. Approximation results presented in this paper show the problem can be approximated with interesting constant ratio on $k$–stage bipartite graphs for $k = 1$ or 2. The presented approach suggests a generalization is possible for $k \geq 3$. This part constitutes one perspective of this work. Other perspective would consists to study coupled-tasks on other significant topologies, including degree-bounded trees, or regular topologies like the grid.
