Abstract

We consider a problem arising in the context of industrial production planning, namely the multi-product discrete lot-sizing and scheduling problem with sequence-dependent changeover costs. We aim at developing an exact solution approach based on a standard Branch & Bound procedure for this combinatorial optimization problem. To achieve this, we propose a new family of multi-product valid inequalities which enables us to better take into account in the mixed integer linear programming formulation the conflicts between different products simultaneously requiring production on the resource. We then present both an exact and a heuristic separation algorithm in order to identify the most violated valid inequalities to be added in the initial MILP formulation within a cutting-plane generation algorithm. We finally discuss preliminary computational results which confirm the practical usefulness of the proposed valid inequalities at strengthening the MILP formulation and at reducing the overall computation time.

1 Introduction

Capacitated lot-sizing arises in industrial production planning whenever change-over operations such as preheating, tool changing or cleaning are required between production runs of different products on a machine. The amount of the
related changeover costs usually does not depend on the number of products processed after the changeover. Thus, to minimize changeover costs, production should be run using large lot sizes. However, this generates inventory holding costs as the production cannot be synchronized with the actual demand pattern: products must be held in inventory between the time they are produced and the time they are used to satisfy customer demand. The objective of lot-sizing is thus to reach the best possible trade-off between changeover and inventory holding costs while taking into account both the customer demand satisfaction and the technical limitations of the production system.

An early attempt at modelling this trade-off can be found in [15] for the problem of planning production for a single product on a single resource with an unlimited production capacity. Since this seminal work, a large part of the research on lot-sizing problems has focused on modelling operational aspects in more detail to answer the growing industry need to solve more realistic and complex production planning problems. An overview of recent developments in the field of modelling industrial extensions of lot-sizing problems is provided in [10].

In the present paper, we focus on one of the variants of lot-sizing problems mentioned in [10], namely the multi-product single-resource discrete lot-sizing and scheduling problem or DLSP. As defined in [6] and [10], several key assumptions are used in the DLSP to model the production planning problem:
- A set of products is to be produced on a single capacitated production resource.
- A finite time horizon subdivided into discrete periods is used to plan production.
- Demand for products is time-varying (i.e. dynamic) and deterministically known.
- At most one product can be produced per period (small bucket model) and the facility processes either one product at full capacity or is completely idle (discrete or all-or-nothing production policy).
- Costs to be minimized are the inventory holding costs and the changeover costs.

In the DLSP, it is assumed that a changeover between two production runs for different products results in a changeover cost. Changeover costs can depend either on the next product only (sequence-independent case) or on the sequence of products (sequence-dependent case). We consider in the present paper the DLSP with sequence-dependent changeover costs (denoted DLSPSD in what follows). Sequence-dependent changeover costs are mentioned in [10] as one of the relevant operational aspects to be incorporated into lot-sizing models. Moreover, a significant number of real-life lot-sizing problems involving sequence-dependent changeover costs have been recently reported in the academic literature: see among others [3] for an injection moulding process, [13] for a textile fibre industry or [5] for soft drink production.

A wide variety of solution techniques from the Operations Research field have been proposed to solve lot-sizing problems: the reader is referred to [2] and [9] for recent reviews on the corresponding literature. The present paper belongs
to the line of research dealing with exact solution approaches, i.e. aiming at providing guaranteed optimal solutions for the problem. A large amount of existing solution techniques in this area consists in formulating the problem as a mixed-integer linear program (MILP) and in relying on a Branch & Bound type procedure to solve the obtained MILP. However the computational efficiency of such a procedure strongly depends on the quality of the lower bounds used to evaluate the nodes of the search tree. In the present paper, we seek to improve the quality of these lower bounds so as to decrease the total computation time needed to obtain guaranteed optimal solutions for medium-size instances of the problem. Within the last thirty years, much research has been devoted to the polyhedral study of lot-sizing problems in order to obtain tight linear relaxations and improve the corresponding lower bounds: see e.g. [11] for a general overview of the related literature and [1, 4, 7, 14] for contributions focusing specifically on the DLSP. However, these procedures mainly focus on the underlying single-product subproblems and thus fail at capturing the conflicts between multiple products sharing the same resource capacity. This leads in some cases to significant integrality gaps for multi-product instances of the DLSPSD. In what follows, we propose a new family of multi-product valid inequalities which enables us to partially remedy this difficulty and discuss both an exact and a heuristic algorithm to solve the corresponding separation problem. To the best of our knowledge, this is one of the first attempts focusing on improving the polyhedral description of multi-product lot-sizing problems.

The main contributions of the present paper are thus twofold. First we introduce a new family of valid inequalities representing conflicts on multi-period time intervals between several products simultaneously requiring production on the available resource. Second we formulate the corresponding separation problem as a quadratic binary program and propose to solve it either exactly by relying on a quadratic programming solver or approximately through a Kernighan-Lin type heuristic algorithm. The results of the preliminary computational results carried out on medium-size instances show that the proposed valid inequalities are efficient at strengthening the linear relaxation of the problem and at decreasing the overall computation time needed to obtain guaranteed optimal solutions of the DLSPSD.

The remainder of the paper is organized as follows. In Section 2, we recall the initial MILP formulation of the multi-product DLSPSD as well as the previously published valid inequalities for the underlying single-product subproblems. We then present in Section 3 the proposed new multi-product valid inequalities and discuss in Section 4 both an exact and a heuristic algorithm to solve the corresponding separation problem. Preliminary computational results are discussed in Section 5.

2 MILP formulation of the DLSPSD

In this section, we first recall the initial MILP formulation of the DLSPSD. We use the network flow representation of changeovers between products, which
was proposed among others by [1], as this leads to a tighter linear relaxation of the problem. We then discuss the valid inequalities first proposed by [14] to strengthen the underlying single-product subproblems.

2.1 Initial MILP formulation

We wish to plan production for a set of products denoted \( p = 1 \ldots P \) to be processed on a single production machine over a planning horizon involving \( t = 1 \ldots T \) periods. Product \( p = 0 \) represents the idle state of the machine and period \( t = 0 \) is used to describe the initial state of the production system.

Production capacity is assumed to be constant throughout the planning horizon. We can thus w.l.o.g. normalize the production capacity to one unit per period and express the demands as integer numbers of production capacity units (see [6] and [8]). We denote \( d_{pt} \) the demand for product \( p \) in period \( t \), \( h_p \) the inventory holding cost per unit per period for product \( p \) and \( S_{pq} \) the sequence-dependent changeover cost to be incurred whenever the resource setup state is changed from product \( p \) to product \( q \).

Using this notation, the DLSPSD can be seen as the problem of assigning at most one product to each period of the planning horizon while ensuring demand satisfaction and minimizing both inventory and changeover costs. We thus introduce the following binary decision variables:
- \( y_{pt} \) where \( y_{pt} = 1 \) if product \( p \) is assigned to period \( t \), 0 otherwise.
- \( w_{pqt} \) where \( w_{pqt} = 1 \) if there is a changeover from product \( p \) to product \( q \) at the beginning of \( t \), 0 otherwise.

This leads to the MILP following formulation denoted DLSPSD0 for the problem.

\[
Z_{DLSPSD} = \min \sum_{p=1}^{P} \sum_{t=1}^{T} h_p \sum_{\tau=1}^{t} (y_{p\tau} - d_{p\tau}) + \sum_{p,q=0}^{P} S_{p,q} \sum_{t=1}^{T-1} w_{p,q,t} \\
\sum_{p=0}^{P} y_{pt} = 1, \quad \forall p, \forall t \\
y_{pt} = \sum_{q=0}^{P} w_{q,p,t} \quad \forall p, \forall t \\
y_{pt} = \sum_{q=0}^{P} w_{p,q,t+1} \quad \forall p, \forall t \\
y_{pt} \in \{0,1\} \quad \forall p, \forall t \\
w_{p,q,t} \in \{0,1\} \quad \forall p, \forall q, \forall t
\]

The objective function (2.1) corresponds to the minimization of the inventory holding and changeover costs over the planning horizon. \( \sum_{\tau=1}^{t}(y_{p\tau} - d_{p\tau}) \) is the inventory level of product \( p \) at the end of period \( t \). Constraints (2.1) impose that the cumulated demand over interval \([1,t]\) is satisfied by the cumulated production over the same time interval. Constraints (2.1) ensure that, in each period, the resource is either producing a single product or idle. Constraints (2.1)-(2.1) link setup variables \( y_{p,t} \) with changeover variables \( w_{p,q,t} \) through equalities which can be seen as flow conservation constraints in a network (see e.g. [1]). They ensure that in case product \( p \) is setup in period \( t \), there is a changeover from another product \( q \) (possible \( q = p \)) to product \( p \) at the beginning of period \( t \) and a changeover from product \( p \) to another product \( q \) (possible \( q = p \)) at the
2.2 Single-product valid inequalities

We now recall the expression of the valid inequalities proposed by [14] for the single product DLSP. We denote $d_{p,t,\tau}$ the cumulated demand for product $p$ in the interval $\{t, \ldots, \tau\}$ and $\Delta_{p,v}$ the $v^{th}$ positive demand period for product $p$. $\Delta_{p,d_{p,1,t+1},t}$ is thus the period with the $v^{th}$ positive unit demand for product $p$ after period $t$ occurs.

$$\sum_{t=1}^{t=\tau} (y_{p\tau} - d_{p\tau}) \geq w - \sum_{v=1}^{w} \left[ y_{p,t+v} + \sum_{\tau=t+v+1}^{\tau=v} \sum_{q \neq p} w_{q,p,\tau} \right] \quad \forall p, \forall t, \forall w \in [1, d_{p,t+1}, T]$$

Constraints (2.2) are valid inequalities for the DLSPSD. The underlying idea is to compute a lower bound on the inventory level of a product $p$ at the end of a period $t$ ($\sum_{\tau=1}^{t} (y_{p\tau} - d_{p\tau})$) by considering both the demands and the resource setup states for this product in the forthcoming periods $\tau = t+1 \ldots \Delta_{p,d_{p,1,t+1}}$. The reader is referred to [14] for a full proof of validity for these inequalities. In the computational experiments to be presented in Section 5, we use a standard cutting-plane generation algorithm to strengthen the formulation DLSPSD0 by adding violated valid inequalities of family (2.2). The resulting improved formulation is denoted DLSPSD1.

Constraints (2.2) can be understood as a way to strengthen the demand satisfaction constraints (2.1) by expressing in a more detailed way the need for each individual product to access the resource in order to satisfy its own demand on a given subinterval of the planning horizon. However, in the resulting DLSPSD1 formulation, the conflicts between different products simultaneously requiring production on the resource are only handled by the single-period capacity constraints (2.1). In what follows, we propose to improve this representation of the conflicts between different products by considering multi-period multi-product valid inequalities.

3 Multi-product valid inequalities for the DLSPSD

We now present the multi-period multi-product valid inequalities proposed to strengthen the linear relaxation of the multi-product DLSPSD.

**Proposition 1**

Let $SP \subset \{0 \ldots P\}$ and $SD \subset \{0 \ldots P\}$ be two disjoint subsets of products. Let $t \in [1, T]$ be a period within the planning horizon and $[1, \theta] \subset [1, T]$ be a time interval including period $t$. The following inequality is valid for the multi-product DLSPSD.

$$\left( \sum_{q \in SD} d_{q,1,\theta} \right) \left( \sum_{p \in SP} y_{pt} \right) \leq \sum_{\tau=1}^{\theta} \tilde{C}_{\tau}$$ (1)
where $\tilde{C}_\tau$ is defined by:

$$\tilde{C}_\tau = \min \left( \sum_{q \in SD} y_{q,\tau}, \sum_{p \in SP} y_{pt} \right), \tau \in [1, t-2] \cup [t+2, \theta]$$

$$\tilde{C}_{t-1} = \sum_{p \in SP, q \in SD} w_{q,p,t}$$

$$\tilde{C}_t = 0$$

$$\tilde{C}_{t-1} = \sum_{p \in SP, q \in SD} w_{p,q,t+1}$$

Before providing the proof for Proposition 1, we briefly explain the idea underlying valid inequalities (1). We choose a subset $SP$ of products. If none of these products is assigned for production in period $t$ (i.e. $\sum_{p \in SP} y_{pt} = 0$), all corresponding valid inequalities are trivially respected. But if one of these products is assigned for production in period $t$ (i.e. $\sum_{p \in SP} y_{pt} = 1$), then we have to make sure that we are able to satisfy the total cumulated demand over the interval $[1, \theta]$ for the products in subset $SD$ (i.e. to satisfy $\sum_{q \in SD} d_{q,1,\theta}$) on the remaining periods $1...t-1, t+1...\theta$. In this case, the right hand side of inequalities (1) computes a tight upper bound of the production capacity available over these periods for the products in $SD$.

Let $(y,w)$ be a feasible solution of the DLPSD. We arbitrarily choose a period $t$, an interval $[1, \theta]$ including $t$ and two disjoint subsets of products $SP$ and $SD$ and show that all proposed inequalities (1) are valid for the considered feasible solution.

We distinguish two main cases:

Case 1: $\sum_{p \in SP} y_{pt} = 0$

In this case, the left hand side of the inequality is equal to 0 whereas the right hand side is nonnegative. Inequality (1) is thus trivially true.

Case 2: $\sum_{p \in SP} y_{pt} = 1$

In this case, the left hand side of inequality (1) is equal to the total cumulated demand over interval $[1, \theta]$ for the products belonging to $SD$, i.e. to $\sum_{q \in SD} d_{q,1,\theta}$.

$\sum_{p \in SP} y_{pt} = 1$ means that period $t$ is devoted to the production of one of the products in $SP$ and thus cannot be used to satisfy the cumulated demand for products in $SD$. Hence $(y,w)$ can be a feasible solution of the DLPSD if and only if the total cumulated production for products in $SD$ over the remaining periods $1...t-1, t+1...\theta$ is sufficient to satisfy the cumulated demand $\sum_{q \in SD} d_{q,1,\theta}$.

We now seek to compute a tight upper bound for the production capacity $C_\tau$ available in each period $\tau \in [1, t-1] \cap [t+1, \theta]$ for the products in $SD$:

- By capacity constraints (2.1), we have $C_\tau \leq 1$, i.e. $C_\tau \leq \sum_{p \in SP} y_{pt}$.
- Moreover, demands for products in $SD$ can only be satisfied by a production for these products, i.e. $\tau$ can be used to satisfy part of demand $\sum_{q \in SD} d_{q,1,\theta}$ only if the resource is setup for one of these products in period $\tau$. This gives $C_\tau \leq \sum_{q \in SD} y_{q,\tau}$.

We thus obtain:

$$C_\tau \leq \min \left( \sum_{q \in SD} y_{q,\tau}, \sum_{p \in SP} y_{pt} \right), \forall \tau \in [1, \theta], \tau \neq t \quad (2)$$

This leads to the following valid inequality stating that, in a feasible solution
of (3) the term for \( \tau \) min case

\[
\sum_{q \in SD} d_{q,1,\theta} \leq \sum_{\tau \in [1,\theta], \tau \neq t} \left[ \min \left( \sum_{q \in SD} y_{q,\tau}, \sum_{p \in SP} y_{p,\tau} \right) \right]
\]

Now, we can exploit our knowledge of the setup state of the resource in period \( t \) to further strengthen this inequality. Namely, we know that a product \( p \) belonging to \( SP \) is produced in period \( t \). A changeover to (resp. from) this product \( p \) thus has to take place at the beginning (resp. at the end) of period \( t \). This means that:

- For \( t \neq 1 \), if a product \( q \) belonging to \( SD \) is produced in period \( t - 1 \), there must be a changeover from this product \( q \in SD \) to the product \( p \in SP \) at the beginning of period \( t \). The production capacity available in period \( \tau = t - 1 \) for the products in \( SD \) is thus limited by \( C_{t-1} \leq \sum_{p \in SP, q \in SD} w_{q,p,t} \leq \min(\sum_{q \in SD} y_{q,t-1}, \sum_{p \in SP} y_{p,t}) \).

- For \( t \neq \theta \), if a product \( q \) belonging to \( SD \) is produced in period \( t + 1 \), there must be a changeover to this product \( q \in SD \) from the product \( p \in SP \) at the end of period \( t \). The production capacity available in period \( \tau = t + 1 \) for the products in \( SD \) is thus limited by \( C_{t+1} \leq \sum_{p \in SP, q \in SD} w_{p,q,t+1} \leq \min(\sum_{q \in SD} y_{q,t+1}, \sum_{p \in SP} y_{p,t}) \).

Depending on the value of \( t \), we can thus replace in the right hand side of (3) the term for \( \tau = t - 1 \) (resp. \( \tau = t + 1 \)) by \( \sum_{p \in SP, q \in SD} w_{q,p,t} \) (resp. \( \sum_{p \in SP, q \in SD} w_{p,q,t+1} \)), which shows the validity of inequalities (1) for the DSLSP.

We point out here that, for any integer feasible solution of the DSLSP, in case \( \sum_{p \in SP} y_{p,t} = 1 \), we have:

\[
\sum_{q \in SD} y_{q,\tau} \leq \sum_{p \in SP} y_{p,t}, \quad \forall \tau \in [1,\theta], \tau \neq t
\]

\[
\sum_{p \in SP, q \in SD} w_{q,p,t} = \sum_{q \in SD} y_{q,t-1}, \quad \text{if } t \neq 1
\]

\[
\sum_{p \in SP, q \in SD} w_{p,q,t+1} = \sum_{q \in SD} y_{q,t+1}, \quad \text{if } t \neq \theta
\]

We will thus have \( C_{\tau} = \sum_{q \in SD} y_{q,\tau}, \forall \tau \in [1,\theta], t-1 [1,\theta] \) in any integer feasible solution of the problem. However, in a fractional solution obtained by solving the linear relaxation of formulation DSLSP, we may encounter situations where \( 0 < \sum_{p \in SP} y_{p,t} < 1 \) so that we may have \( \sum_{p \in SP} y_{p,t} \leq \sum_{q \in SD} y_{q,\tau}, \sum_{p \in SP, q \in SD} w_{q,p,t} \leq \sum_{q \in SD} y_{q,t-1} \) and \( \sum_{p \in SP, q \in SD} w_{p,q,t+1} \leq \sum_{q \in SD} y_{q,t+1} \). In these cases, it is interesting to have the flexibility to select for each period \( \tau \) the smallest upper bound for the available production capacity \( C_{\tau} \) as this will lead to tighter valid inequalities.

### 4 Exact and heuristic algorithms for solving the separation problem

The number of valid inequalities (1) grows very fast with the problem size. Namely, we have a series of valid inequalities for the \( \frac{(T+1)T}{2} \) pairs of periods
$(t, \theta)$ with $t \leq \theta$. Moreover, for a given pair of periods $(t, \theta)$, the number of available valid inequalities is given by $3\text{Part}(P + 1, 3)$. Here $\text{Part}(P + 1, 3)$ is the number of partitions of a set of $P + 1$ elements into 3 subsets ($SP$, $SD$ and \{0...P\} \setminus (SD \cap SP)$) and can be computed by a mathematical induction. Thus, for an instance involving e.g. $P = 10$ products and $T = 25$ periods, we have $0.5 \times 26 \times 25 \times 3 \times 28501 = 27788475$ valid inequalities.

It is therefore not possible to include them a priori in the MILP formulation of the problem. This is why we use a cutting-plane generation strategy to add to the MILP formulation only the most violated valid inequalities of the family. This requires solving the corresponding separation algorithm which, given a fractional solution $(\bar{y}, \bar{w})$ of the DLSPSD, will either identify a violated valid inequality or prove that no such inequality exists.

### 4.1 Exact separation algorithm

We first discuss an exact separation algorithm, i.e. an algorithm which is guaranteed to find an inequality violated by the fractional solution $(\bar{y}, \bar{w})$ if one exists. We consider each possible pair of periods $(t, \theta)$ and look for the partition of \{0...P\} into 3 subsets which provides the largest violation of inequalities (1). To achieve this, we formulate the separation problem for a given $(t, \theta)$ as follows.

We first introduce the following decision variables:

- $\alpha_p = 1$ if product $p$ belongs to subset $SP$, 0 otherwise.
- $\beta_p = 1$ if product $p$ belongs to subset $SD$, 0 otherwise.
- $\gamma_\tau = 1$ if capacity $C_\tau$ is limited by $\sum_{p=0}^{P} y_{p,t} \alpha_p$, 0 if $C_\tau$ is limited by $\sum_{q=0}^{P} y_{q,\tau} \beta_q$.

With this notation, the separation problem for a given $(t, \theta)$ and a solution $(\bar{y}, \bar{w})$ is formulated as the following quadratic binary program $QBP_{t,\theta}$:

$$
\text{max} \quad \sum_{p=0}^{P} \sum_{q=0}^{P} \left[ d_{q,1,\theta} - w_{q,p,t} - w_{p,q,t+1} \right] \alpha_p \beta_q \\
- \sum_{\tau=1}^{t-2} \left[ \sum_{p=0}^{P} y_{p,\tau} \alpha_p \gamma_\tau + \sum_{q=0}^{P} y_{q,\tau} \beta_q (1 - \gamma_\tau) \right] \\
- \sum_{\tau=t+2}^{T} \left[ \sum_{p=0}^{P} y_{p,\tau} \alpha_p \gamma_\tau + \sum_{q=0}^{P} y_{q,\tau} \beta_q (1 - \gamma_\tau) \right] \\
\alpha_p + \beta_p \leq 1 \quad \forall p = 0...P \\
\alpha_p \in \{0,1\}, \beta_p \in \{0,1\} \quad \forall p = 0...P \\
\gamma_\tau \in \{0,1\} \quad \forall \tau = 1...T
$$

The objective function (4.1) corresponds to the maximization of the violation of the inequalities, i.e. we seek to identify the subsets $SP$ and $SD$ for which the difference between the left hand side and the right hand side of the inequality takes the largest value. If this value is strictly positive, we obtain a violated valid inequality corresponding to $(t, \theta, SP, SD)$. In case this value is less than or equal to 0, it means that all valid inequalities for $(t, \theta)$ are satisfied by the fractional solution $(\bar{y}, \bar{w})$. Constraints (4.1) state that a given product $p$ cannot be simultaneously included in subsets $SP$ and $SD$.

Problem $QBP_{t,\theta}$ is a binary program with a quadratic objective function and a series of linear constraints. It can be solved to optimality by a mixed-integer quadratic programming solver such as the one embedded in CPLEX 12.5.
4.2 Heuristic separation algorithm

As can be seen from the computational experiments to be presented in Section 5, solving to optimality a sequence of quadratic binary programs $QBP_{t,\theta}$ leads to prohibitively long computation times for the cutting-plane generation algorithm, even for small-size instances. This is why we propose in what follows a Kernighan-Lin type heuristic which enables us to more quickly identify a violated valid inequality for a given pair $(t, \theta)$.

Start with a tripartition of $\{0...P\}$, $\Pi_{ref}$, and compute its violation $V_{ref}$.

While $(test = 0)$:
- Let $test = 1$, $PossMove = P + 1$ and $\Pi_{cur} = \Pi_{ref}$.
- Allow all possible moves to explore the neighbourhood of $\Pi_{cur}$.
- While ($PossMove > 0$):
  - Consider the partitions obtained by carrying out all allowed moves in the neighbourhood of $\Pi_{cur}$ and evaluate the violation for each obtained partition.
  - Select the best partition obtained in this neighbourhood of $\Pi_{cur}$, $\Pi_{best}$, forbid the move used to obtain $\Pi_{best}$ from $\Pi_{cur}$, decrease $PossMove$ by 1 and set $\Pi_{cur} = \Pi_{best}$.
- If $V_{best} > V_{ref}$, $test = 0$ and $\Pi_{ref} = \Pi_{best}$.

The neighbourhood of a tripartition $\Pi$ of $\{0...P\}$ is defined as the set of tripartitions obtained by moving a single product from its current subset in $\Pi$ to one of the two other subsets. Moreover, in the computational experiments to be presented in Section 5, five different types of partitions are used to initialize the heuristic.

4.3 Cutting-plane generation algorithm

We now briefly describe the cutting-plane generation used to strengthen formulation DLSPSD1 by adding to it some multi-product valid inequalities (1).
Compute the initial LP relaxation of the DLSPSD using formulation DLSPSD1.

While (test = 0):
    Denote \((\bar{y}, \bar{w})\) the solution of the current linear relaxation.
    For \(t=1...T\) such that \(\exists p\) such that \(0.0001 < \bar{y}_{pt} < 0.9999\);
    Let \(\theta = t\) and \(found = 0\).
    While (\(\theta \leq T\)) and (\(found == 0\)),
        Solve the separation problem for periods \((t, \theta)\) using either:
        the exact algorithm or the heuristic algorithm with
        one of the 5 predefined initial partitions.
        If a violated valid inequality has been found, let
        \(found = 1\).
        \(\theta = \theta + 1\).
    If at least one violated valid inequality is found, add all the
    found violated valid inequalities to the current formulation
    and compute its LP relaxation.
    Else set test = 1 to stop the cutting-plane generation.

5 Preliminary computational results

We now discuss the results of some preliminary computational experiments car-
ried out to evaluate the effectiveness of the proposed multi-product valid in-
equalities at strengthening the formulation of the multi-product DLSPSD and
and to assess their impact on the total computation time.
We randomized generated instances of the problem using a procedure similar to
the one described in [12] for the DLSP with sequence-dependent change-over
costs and times. More precisely, the various instances tested have the following
characteristics:
- Problem dimension. The problem dimension is represented by the number
  of products \(P\) and the number of periods \(T\); we solved medium-size instances
  involving 4 to 10 products and 15 to 75 periods.
- Inventory holding costs. For each product, inventory holding costs have been
  randomly generated from a discrete uniform \(DU(5,10)\) distribution.
- Changeover costs. We used two different types of structure for the changeover
  cost matrix \(S\). Instances of sets A1-A7 have a general cost structure: the cost of
  a changeover from product \(p\) to product \(q\), \(S_{pq}\), was randomly generated from a
  discrete uniform \(DU(100,200)\) distribution. Instances of sets B1-B7 correspond
  to the frequently encountered case where products can be grouped into product
  families: there is a high changeover cost between products of different families
  and a smaller changeover cost between products belonging to the same family.
  In this case, for products \(p\) and \(q\) belonging to different product families, \(S_{pq}\)
  was randomly generated from a discrete uniform \(DU(100,200)\) distribution;
  for products \(p\) and \(q\) belonging to the same product family, \(S_{pq}\) was randomly
  generated from a discrete uniform \(DU(0,100)\) distribution.
- Production capacity utilization. Production capacity utilization \(\rho\) is defined as
the ratio between the total cumulated demand \(\sum_{p=1}^{P} \sum_{t=1}^{T} d_{pt}\) and the total cumulated available capacity \(T\). We set \(\rho = 0.95\) for all instances.

- **Demand pattern.** Binary demands \(d_{pt} \in \{0, 1\}\) for each product have been randomly generated according to the following procedure:

1. We randomly select a product \(p^*\) from a discrete uniform \(DU(1, N)\) distribution and set \(d_{p^*T} = 1\).
2. For each product \(p\), except product \(p^*\), we randomly select a period \(t_p\) from a discrete uniform \(DU(1, T)\) distribution and set \(d_{p,t_p} = 1\).
3. For each entry in a \(P \times T\) matrix, except for the entries corresponding to the \((p, t)\) combinations for which we set \(d_{pt} > 0\) in steps 1 or 2, we randomly generate a number \(\alpha_{pt}\) from a discrete uniform \(DU(1, PT)\) distribution.
4. While the total cumulated demand \(\sum_{p=1}^{P} \sum_{t=1}^{T} d_{pt}\) does not exceed \(\rho T\), we consider the entries \((p, t)\) one by one in the increasing order of the corresponding value \(\alpha_{pt}\) and set \(d_{pt} = 1\).
5. When the total cumulated demand reaches \(\rho T\), we examine whether the corresponding instance is feasible by checking that \(\sum_{p=1}^{P} \sum_{r=1}^{t} d_{pr} \leq t\) for all \(t\). If the instance is infeasible, we repeat steps 1 to 4.

For each considered problem dimension, we generated 10 instances, leading to a total of 140 instances.

All tests were run on an Intel Core i5 (2.7 GHz) with 4 Go of RAM, running under Windows 7. We used a standard MILP software (CPLEX 12.5) with the solver default settings to solve the problems with one of the following formulations:

- **DLPSD1:** initial MILP formulation DLSPSDo, i.e. formulation (2.1)-(2.1), strengthened by single-product valid inequalities (2.2). We used a standard cutting-plane generation strategy based on a complete enumeration of all possible valid inequalities to add them into the formulation.

- **DLSPSD2e:** formulation DLPSD1 strengthened by multi-product valid inequalities (1). We used the cutting-plane generation algorithm presented in Section 4.3 to add only the most violated valid inequalities and relied on the exact separation algorithm discussed in Section 4.1.

- **DLSPSD2h:** formulation DLPSD1 strengthened by multi-product valid inequalities (1). We used the cutting-plane generation algorithm presented in Section 4.3 to add only the most violated valid inequalities and relied on the heuristic separation algorithm discussed in Section 4.2.

Tables 1 and 2 display the computational results. We provide for each set of 10 instances:

- **\(P\) and **\(T\): the number of products and planning periods involved in the production planning problem.
- **\(V\) and **\(Cst\): the number of variables and constraints in the initial formulation DLSPSD0.
- **\(SP\): the number of single-product violated valid inequalities (2.2) added in

Results from Table 1 show that the proposed valid inequalities (1) are efficient at strengthening formulation DLSPSD1. Namely, the integrality gap is reduced from an average of 5.3% with formulation DLSPSD1 (see \( \text{Gap}_{LP1} \)) to an average of 0.5% with formulation DLSPSD2e (see \( \text{Gap}_{LP2e} \)). We note that this reduction is particularly significant for instances B1-B3 featuring a product family changeover cost structure. Moreover this formulation strengthening is obtained thanks to a relatively small number of multi-product inequalities as can be seen from the average value of \( \text{MPe} \) (13). However, even if the number of nodes needed by the Branch & Bound procedure to find a guaranteed optimal integer solution is slightly reduced when using formulation DLSPSD2e, it does not lead to an overall reduction of the computation time. This is mainly explained by the fact that the cutting-plane generation algorithm based on an exact separation algorithm requires prohibitively long computation times to identify the violated multi-product valid inequalities to be added to the formulation. It is thus necessary to resort to a heuristic separation algorithm such as the one proposed in Section 4.2.

Comparison of the results obtained with the exact and the heuristic separation algorithm for the instances A1-A3 and B1-B3 (Tables 1 and 2) shows that the proposed heuristic is very efficient at finding violated valid inequalities for small size instances. Namely, the average integrality gap for these 60 instances when using the heuristic algorithm is the same as the one when using the exact algorithm (i.e. \( G_{lp,p,e} = G_{lp,p,h} \)). Moreover, the number of violated valid inequalities found by the heuristic algorithm is nearly the same as the number of violated valid inequalities found by the exact algorithm.

Results from Table 2 also confirm that the proposed heuristic is rather efficient at finding violated valid inequalities for larger instances. This can be seen by looking at the results for instances A4-A7 and B4-B7. We first note that, for these instances, the integrality gap is reduced from an average of 7.9% while using formulation DLSPSD1 to an average of 4.7% while using formulation DLSPSD2h. Moreover a significant decrease in the overall computation time is obtained for instances B4-B7 when using formulation DLSPSD2h.

6 Conclusion

We considered the multi-product discrete lot-sizing and scheduling problem with sequence-dependent changeover costs and proposed a new family of multi-product valid inequalities for this problem. This enabled us to better take into account in the MILP formulation the conflicts between different products simultaneously requiring production on the resource. We then presented both an exact and a heuristic separation algorithm in order to identify the most violated valid inequalities to be added in the initial MILP formulation within a
cutting-plane generation algorithm. Our preliminary results show that the proposed valid inequalities are efficient at strengthening the MILP formulation and that their use leads to a significant reduction of the overall computation time for instances featuring a product family changeover cost structure. Additional computational experiments are currently carried out to confirm these promising results.
