(Received 13 June 2002; published 27 November 2002)

We report on specific-heat, high-magnetic-field transport, and ac-susceptibility measurements on MgB$_2$ single crystals. The upper critical field for magnetic fields perpendicular and parallel to the basal planes is presented in the entire temperature range. A very different temperature dependence has been observed in the two directions, which yields a temperature-dependent anisotropy with $\Gamma = 5$ at low temperatures and $\sim 2$ near $T_c$. A peak effect is observed for $\mu_0H \sim 2$ T parallel to the c axis, and the critical current density presents a sharp maximum for $H$ parallel to the ab plane.

Since the discovery of superconductivity in magnesium diboride at 39 K in 2001 (Ref. 1) an enormous amount of work has been done, which helped to elucidate many of its physical properties. Among others, the two-band superconductivity2 has been confirmed by different techniques such as specific heat3 or Andreev reflection.3 This picture suggests a significant anisotropy of the superconducting state but data reported on the anisotropy of the upper critical field $H_{c2}$ scatter from 1.1 to 13, depending on the form of material (polycrystals, thin films, single crystals) and method of evaluation. The problem thus remains to be clarified on high-quality single crystals.

We have determined $H_{c2}$ in MgB$_2$ single crystal for $H$ parallel and perpendicular to the ab planes by magnetotransport (down to 5 K and up to 28 T), ac-susceptibility (up to 5 T), and specific heat (up to 7 T) measurements. $H_{c2,ab}$ reveals a classical linear temperature dependence near $T_c$ [with $\mu_0H_{c2,ab}(0) \approx 3.5$ T], while $H_{c2,\perp}$ shows a positive curvature at temperatures above 20 K and saturates at $\mu_0H_{c2,\perp}(0) = 17$ T. As a consequence $\Gamma = H_{c2,\perp}/H_{c2,ab}$ is temperature dependent with $\Gamma(0 \text{ K}) = 5$ and $\Gamma(\text{near } T_c) \approx 2$. On the other hand, the critical current deduced from ac-susceptibility measurements presents a sharp maximum for $H_{||ab}$.

Experiments have been performed on high-quality MgB$_2$ single crystals5 showing clear hexagonal facets with flat and shiny surfaces (of typical dimensions 50×50×10 µm$^3$). Four-probe magnetoresistance measurements have been performed for different temperatures and angles ($\theta$) between $H$ and the ab planes. Gold electrodes have been evaporated as stripes overlapping the top plane of the sample with a contact resistance of $\sim 1$ Ω, and $H$ was always orthogonal to the measuring current. The ac susceptibility has been deduced from the local transmittivity measured with a miniature Hall probe. The ac excitation field ($h_{ac} \sim 3$ G, $\omega \sim 23$ Hz) was perpendicular to the ab plane and to the Hall-probe plane, and superimposed over a dc field with an angle $0 < \theta < 90°$. The specific heat was measured by an ac technique.5 Heat was supplied to the sample at a frequency $\omega$ of the order of 70 Hz by a light-emitting diode via an optical fiber. The induced temperature oscillations were measured by a 12-µm-diameter chromel-constantan thermocouple calibrated in situ.

Figure 1 displays the temperature dependence of the field-dependent part of the specific heat up to 7 T for $H_{||ab}$ and up to 2 T for $H_{\perp ab}$. In zero field, the specific-heat discontinuity at $T_c$ represents about 3% of the total signal. This value is five to six times smaller than that obtained in the best polycrystalline samples,5 which can be attributed to the large contribution of the addenda, given the extremely small

![FIG. 1. Temperature dependence of the specific heat at different magnetic fields for $H_{||ab}$ (closed circles) and $H_{\perp ab}$ (open squares). Inset: specific-heat transition at $\mu_0H_{||ab} = 1$ T and $\mu_0H_{||ab} = 17$ T.](image-url)
size of our single crystals (∼100 ng). The data are therefore given in arbitrary units and the temperature range is limited to T > 12 K. No significant increase of the transition width, ΔT ~ 2 K, is observed for $\mu_0 H|_{c<2}$ T and $\mu_0 H|_{ab}$ < 5 T. Despite a clear broadening at higher fields, the specific-heat anomaly remains well defined in our explored temperature range. This implies that the broadening observed in polycrystalline samples is due to randomly oriented anisotropic grains rather than thermodynamic fluctuations. The curves are remarkably identical for both directions once the field is temperature dependent, de-
only reaches its normal-state value \( (R_N) \) for a higher field \( H_{R_N} \). For \( H_{R_N} > H > H_{c2} \), the highly non-Ohmic current dependence of the transition has been attributed to surface conductivity by some of us.\(^9\) As shown in Fig. 3, for low current densities \( (j = 17, 50, \text{ and } 170 \, \text{A/cm}^2) \) the transitions are smooth for both field orientations and, for \( H \perp ab \), the onset of finite resistivity even shifts towards higher fields as the current density is decreased. This onset becomes sharp and current independent above \( 500 \, \text{A/cm}^2 \) for \( H \perp ab \) and \( 170 \, \text{A/cm}^2 \) for \( H \parallel ab \). The ratio between the fields \( H_{R=0} = H_{c2} \) \( (j = 500 \, \text{A/cm}^2) \) and \( H_{R_N} \) (measured at the lowest current) is about 1.8 for \( H \perp ab \) and 1.4 for \( H \parallel ab \). This ratio remains constant for all temperatures apart from those very close to \( T_c \), where it is affected by the width of the transition \( \Delta T_c \).

For \( H \parallel ab \), our data are strikingly similar to those obtained by Hempstead and Kim\(^15\) in their pioneering work on surface superconductivity in \( \text{Nb}_{0.5} \text{Ta}_{0.5} \) and \( \text{Pb}_{0.8} \text{In}_{0.17} \) sheets. The resistive transition can be analyzed as follows: up to some characteristic \( j \) value, the onset of finite resistance is sensitive to \( j \) due to the existence of a surface sheath which can bear a current keeping the zero resistance above \( H_{c2} \). For higher \( j \) values, this sheath is destroyed and the resistance increases sharply at \( H = H_{c2} \) to a fraction of \( R_N \) which increases with \( j \). For the lowest \( j \) values, \( H_{R_N} = H_{c3} \approx 1.7 H_{c2} \), but the experimental \( H_{c3} / H_{c2} \) ratio in Ref. 15 was scattered between 1.6 and 1.96 and even dropped down to 1.14 for copper coated \( \text{Pb-In} \) sheets. Surface superconductivity effects should be negligible for \( H \parallel ab \), but in our experimental setup, the current and voltage electrodes overlapping the sample go over the vertical side planes, which thus inevitably contribute to surface superconductivity as well.\(^16\)

With triangles, we have plotted in Fig. 4 the angular dependence of \( H_{R_N} \) at \( T = 5.4 \, \text{K} \). If surface conductivity is important for \( H \perp ab \) and \( H \parallel ab \), this effect is diminished for other field orientations and \( H_{R_N} / H_{c2} \) drops down to \( \approx 1.1 \). This increase of surface conductivity close to the \( ab \) planes can thus account for the cusplike behavior of \( H_{R_N} \) at small angles which has been first attributed to \( H_{c2} \) by other authors.\(^17,18\)

The anisotropy of \( H_{c2} \) in \( \text{MgB}_2 \) crystals has been measured recently by several authors in a limited temperature range by either magnetometric\(^19,20\) or thermal-conductivity\(^21\) measurements. Those measurements yield results very similar to ours, but it was of fundamental importance to show that the “critical fields” obtained from all those measurements coincide with the thermodynamic transition field deduced from specific-heat measurements. Indeed, in many novel superconductors, fluctuations broaden the transitions from the superconducting to the normal state. One of the most striking phenomenon that has been observed in these systems is the existence of a melting line \( T_m(H) \). The presence of this vortex liquid phase above \( T_m \) complicates the determination of the upper critical field \( H_{c2} \). For instance, the onset of a finite \( R \) in these systems indicates the melting transition, and \( H_{c2} \) is shifted to a much higher resistance (close to \( R_N \); see, for instance, Ref. 22). However, fluctuations are not expected to play any significant role in \( \text{MgB}_2 \) as confirmed by specific-heat measurements. A incorrect criterion for the \( H_{c2} \) determination partly explains the discrepancy in the \( H_{c2} \) values deduced from transport measurements.\(^23,17\)

Another interesting phenomenon is the observation of a peak effect in the critical current \( (J) \), which shows up in our transport data in the same way as in Ref. 9. Similarly, this increase in \( J \) appears as a dip in our ac-susceptibility measurements, which could be observed for \( H \perp ab \) in a narrow magnetic-field range \( \approx 2–3 \, \text{T} \) (see inset of Fig. 5). As recently reported by Pissas et al.,\(^24\) this dip is replaced by a sharp drop for lower magnetic fields and has been attributed to a possible melting of the vortex solid,\(^24\) in contradiction with our specific-heat data, which show that the onset of diamagnetism actually coincides with the \( H_{c2} \) line. As shown in Fig. 5, the \( J \) value at the peak position—deduced from the susceptibility, following the procedure introduced by Pasquini et al.,\(^25\) rapidly decreases for increasing temperature (i.e., for decreasing magnetic field). Similarly, as shown in the inset of Fig. 5, the peak effect also “disappears” in the susceptibility measurements when the magnetic field is turned away from the \( c \) axis. However, this peak is still visible in our transport measurements for \( H \parallel ab \), suggesting that it could exist for all \( H \) and \( \theta \) values. In \( \text{MgB}_2 \) this effect most probably reflects the fact that the shear energy of the flux lattice drops towards zero more rapidly than the pinning energy in the vicinity of the normal state, allowing the vortex matter to accommodate the disorder close to the transition more efficiently.\(^26\)

Our \( J \) values for \( H \perp ab \) are much smaller than those previously obtained in polycrystals.\(^27\) However, as shown in the inset of Fig. 5, if the susceptibility only weakly depends on \( \theta \) down to \( \approx 10^\circ \), it decreases rapidly close to the \( ab \) plane,
showing that the pinning of the vortices is much more efficient for $H | ab$. The corresponding $J$ values at 18 K are displayed in the inset of Fig. 4, showing that $J$ increases by a factor of about 4 for $H | ab$. A similar behavior has been observed in the critical current deduced from transport measurements in $c$ axis oriented thin films$^{28}$ and Eltsev et al. recently reported on a rapid drop of the dissipation when the magnetic field is applied parallel to the $ab$ planes in single crystals.$^{17}$ A similar cusp in the critical current has been observed in high-$T_c$ cuprates in which vortices are strongly pinning by the weakly superconducting layers between the CuO$_2$ planes when the field is applied parallel to those planes (so-called intrinsic pinning$^{29}$). However, the origin of the strong pinning of the $ab$ planes in diborides still has to be clarified, given the rather small anisotropy of this material.

In summary, the upper critical field has been deduced from specific-heat, high-magnetic-field transport, and ac-susceptibility measurements for $H || ab$ parallel and perpendicular to the $ab$ planes. $H_{c2 || ab}$ reveals a conventional temperature dependence with $\mu_0 H_{c2 || ab}(0) \approx 3.5$ T, but the parallel critical field has a positive curvature above 20 K and saturates at $\mu_0 H_{c2 || ab}(0) \approx 17$ T. Consequently, the anisotropy factor $\Gamma$ is temperature dependent, decreasing from $\sim 5$ at low temperature to $\sim 2$ close to $T_c$. The critical current deduced from the susceptibility measurements presents a peak effect for $\mu_0 H_{ab} \sim 2 - 3$ T and rapidly increases for $H || ab$.

16. Reference 9 has discussed possible arguments for weaker surface superconductivity effects in the $H || ab$ configuration based on surface electronic states in MgB$_2$.
