ABSTRACT

Ultrafine particulate matters enriched with metals are emitted into the atmosphere by industrial activities and can impact terrestrial and aquatic ecosystems. Thus, this study investigated the environmental effects of process particles from a lead-recycling facility after atmospheric deposition on soils and potential run-off to surface waters. The toxicity of lead-enriched PM for ecosystems was investigated on lettuce and bacteria by (i) germination tests, growth assays, lead transfer to plant tissues determination and (ii) Microtox analysis.

The influence of ageing and soil properties on metal transfer and ecotoxicity was studied using three different soils and comparing various aged, spiked or historically long-term polluted soils. Finally, lead availability was assessed by 0.01 M CaCl₂ soil extraction.

The results showed that process PM have a toxic effect on lettuce seedling growth and on *Vibrio fischeri* metabolism. Soil-PM interactions significantly influence PM ecotoxicity and bioavailability; the effect is complex and depends on the duration of ageing. Solubilisation or stabilisation processes with metal speciation changes could be involved. Finally, Microtox and phytotoxicity tests are sensitive and complementary tools for studying process PM ecotoxicity.

1. Introduction

During the last decade, the proportion of fine and ultrafine particulate matter enriched with metals and metalloids (PM) has increased in the troposphere with the development of recycling activities (Nair et al., 2010) and the use of more effective filters in facilities (Zhang et al., 2005). Thus, sectors of the metal industry, such as secondary smelters that recycle batteries, release fine lead-enriched particles into the atmosphere (Batonneau et al., 2004; Uzu et al., 2009). As reported by Cecchi et al. (2008), the different stages of the recycling process (crushing, fusion, reduction and refining) in these facilities generate undesirable by-products enriched with metals and metalloids. These elements have been for the most part classified as Substances of Very High Concern (SVHC) in the European REACH law (Regulation EC 1907/2006 of the European Parliament and of the Council of 18 December 2006). Since then, studies have been devoted to the health implications of PM

exposure (Brook et al., 2002; Nel et al., 2006; Sammut, 2007; Polichetti et al., 2009; Perrone et al., 2010).

These fine and ultrafine particles, including nanoparticles, can be transported over long distances in the troposphere (Fernández Espinosa et al., 2002), and due to a high surface/volume ratio (inducing numerous reactive sites), PM could present a greater impact on the biosphere than coarse particles, including atmospheric (Ohmsen, 2001; Batonneau et al., 2004; Nel et al., 2006) and soil contamination (Donisa et al., 2000; Ma et al., 2010a,b). Moreover, carried from the air as fine particles, metals could be easily released in soil solution, then transferred to the surface or sub-surface waters by erosion and run-off. PM transfer from the atmosphere and/or soil to plants (Lin and Xing, 2008; Uzu et al., 2009, 2010), phytotoxicity (Lin and Xing, 2007; Vila et al., 2007), ecotoxicity for microbial communities (Doshi et al., 2008; Strigul et al., 2009) and the impact on the aquatic environment (Moore, 2006; Barrena et al., 2009; Strigul et al., 2009) have recently been considered.

However, most of available studies deal with synthetic manufactured specific species (metal, oxide or sulphate fine particles) such as TiO₂ (Warheit et al., 2007), Ag, Fe₃O₄ and Au (Barrena et al., 2009), Al₂O₃ (Yang and Watts, 2005), as well as Zn and ZnO (Lin and Xing, 2007). The recent literature has poorly reported works

using process PM. Moreover, the impact of PM on the terrestrial ecosystem could also depend on soil characteristics (texture, pH, organic matter, etc.) and interactions between soil and particulate matter (complexation, fixation, dissolution, mobility, bio-accessibility, etc.) as reported by Richards et al. (2000). Nevertheless, in many experimental set-ups, the effect of PM on plant development was tested using hydroponic assays with a nutritive solution or wet paper on petri dishes (Lin and Xing, 2007, 2008; Stampoulis et al., 2009; Ma et al., 2010a,b) instead of polluted soils as the substrate for plant growth. These laboratory experiments often involve the use of chemicals such as solvents for PM dispersion in nutritive solutions. In addition, according to Jalali and Khanlari (2008) or Zapusek and Lestan (2009), pollution age could modify the impact of PM.

So, the objective of this work was to study the influence of soil-PM interactions and ageing on PM bioavailability and ecotoxicity. Germination tests, growth assays, lead phytoavailability (measured in plant tissues and assessed by CaCl_2 extraction) and Microtox analysis were performed in relation to soil types and ageing conditions: (i) PM-spiked soils, (ii) PM-spiked soils aged for 3 months and (iii) long-term historically polluted soil.

2. Materials and methods

2.1. Particulate matter

2.1.1. Particle sampling from the smelter

Process particles were collected from a secondary lead smelter at the Chemical Metal Treatment Company (STCM) which currently recycles batteries. The facility is located in the urban area of Toulouse, in the southwest of France ($43^\circ38'12''\text{N}$, $01^\circ25'34''\text{E}$). As described by Uzu et al. (2009), three different sources of particles have been identified in the smelter. Our study focused on the channelled emissions of particles from the rotary furnaces at 1200°C because these PM are the finest and are potentially released into the atmosphere where they can become toxic to the environment. Particles were collected in polyethylene bags, transferred in sealed opaque containers and stored at 4°C until all experiments.

2.1.2. Particle characteristics

The size distribution of the particles was determined by laser granulometric analyses using a Malvern Mastersizer S, which permitted particle size measurements in the range of $0.05\text{--}900\ \mu\text{m}$. Dust samples were dispersed in alcohol to avoid potential hydrophobic agglomeration and sonicated for 10 min (Sammur, 2007).

Particles from the channelled emissions of rotary furnaces could be segregated into three size ranges. Expressed as volume fractions, the majority of PM (89%) were in the $1\text{--}100\ \mu\text{m}$ range, 7% were inferior to $1\ \mu\text{m}$ (sub-micronic and nanoparticles) and 4% were superior to $100\ \mu\text{m}$ (Uzu et al., in press).

For the present experiments, industrial particles were not size-segregated in order to retain the real conditions of smelter atmospheric emissions. Heated digestion of the particulate matter was performed with standard acid (HNO_3 , HCl , HF , Suprapur, Merck) in a PTFE vessel and filtration (Millex syringe $0.22\ \mu\text{m}$) was performed as described by Uzu et al. (2009, in press). Elemental total contents were then determined in furnace emissions on an ICP-OES IRIS Intrepid II XXDL. Major elements found in the samples were, by mass: Pb (27%), O (15%) and S (7.5%) with no significant differences according to particle size. Several other secondary metals: Cd (2.5%), Zn (0.5%), Fe (0.1–0.4%) and Sb (0.1%) were also present (Uzu et al., in press). The remaining elements to complete 100% were for the most part chloride, sodium, carbon and other metals such as Al, As, Cu and Ni recorded as traces. According to Uzu

et al. (2009, in press), particles are mainly composed of metallic sulphides, sulphates, oxides and perchlorates; lead speciation was, in decreasing order of abundance: PbS , PbSO_4 , $\text{PbO}\cdot\text{PbSO}_4$, $\alpha\text{-PbO}$ and Pb^0 .

2.2. Soil spiking and ageing processes

For this experiment, three different soils (annotated soil-1, soil-2 and soil-3) were sampled in the peri-urban zone of Toulouse: soil-1, $43^\circ35'57.24''\text{N}$, $1^\circ23'41.15''\text{E}$; soil-2, $43^\circ31'50.94''\text{N}$, $1^\circ30'19.62''\text{E}$ and soil-3, $43^\circ31'36.54''\text{N}$, $1^\circ30'28.48''\text{E}$. They were air dried and sieved through a 2 mm stainless steel sieve. Acidic digestion and IC-P_OES analyses were performed to confirm the absence of trace metallic element contamination. These soils were chosen in view of determining the influence of their characteristics (pH, cation exchange capacity, organic matter, etc.) on the toxicity of industrial micro and sub-micronic particles after deposition. Table 1 summarises the soil properties.

Soils were amended with metallic particles from the smelter emissions with up to three different concentrations of lead: $[\text{Pb}] = 825 \pm 15\ \text{mg kg}^{-1}$ (C_1); $[\text{Pb}] = 1650 \pm 20\ \text{mg kg}^{-1}$ (C_2) and $2475 \pm 20\ \text{mg kg}^{-1}$ (C_3). These corresponds respectively to 1.5, 3 and 4.5 g of PM added to 500 g of soil (Uzu et al., 2009). Agitation was performed overnight. Extra boxes containing soils without PM addition were prepared as controls. After spiking and before all the experiments, soils were kept in the dark at 4°C .

The ageing effect was investigated throughout the comparison between both spiked and historic long-term pollution soils, and by a comparison of soils with various ageing times. Actually, a soil historically polluted by battery recycling emissions ($[\text{Pb}] = 1650 \pm 20\ \text{mg kg}^{-1}$) for 30 years (called soil-4) was also used. Its properties (CEC, granulometry, pH of soil solution) were summarised in Table 1 and had in common at least one characteristic of the other soils. Soil-4 was a grass-covered topsoil (0–30 cm) from a meadow, collected just in the front of a lead-recycling plant, already described by Cecchi (2008). C_2 concentration was chosen as comparable to that of long-term polluted soil-4. For some boxes, with the C_2 concentration, ageing was performed in the greenhouse for 3 months: the day/night temperature regime was $23^\circ\text{C}/19^\circ\text{C}$ and the relative humidity was maintained at 70% by weighing the boxes and adding distilled water daily (Lu et al., 2009). According to Lock and Janssen (2002), this process was preferred to the accelerated ageing effect made in the laboratory (seasonal simulation) described by Udovic and Lestan (2009) in view of retaining more realistic conditions of particle deposition.

2.3. Seed germination and growth assays

The germination tests and growth assays were performed to investigate PM phytotoxicity (Wang et al., 2001; Ma et al., 2010a,b). Commercial seeds of lettuce (cultivar “Batavia Blonde dorée”) were chosen for phytotoxicity tests because lettuce is considered as the most consumed vegetable in the group of leafy vegetables (Křístková et al., 2008). It is almost exclusively used as a fresh vegetable in salads, but some forms are also cooked (Rubatzky and Yamaguchi, 1997; Lebeda et al., 2007). Lettuce is produced commercially in many countries worldwide and is also widely grown as a vegetable in home gardens (Rubatzky and Yamaguchi, 1997). Moreover, this plant is commonly used in recent studies on soil contamination by metals (Alexander et al., 2006; Lin and Xing, 2007; Khan et al., 2008; Uzu et al., 2009).

The germination test was carried out with lettuce seeds that were first immersed in a 10% sodium hypochloride solution for 10 min to ensure surface sterility (according to Lin and Xing, 2007). Then, spiked and control soils, 200 g dry weight equivalent, were placed in plastic pots (Kreysa and Wiesner, 1995; Gong et al.,

Table 1

Properties of the four different soils used for ecotoxicity experiments.

	Granulometry (%)					pH	Organic matter (g kg ⁻¹)	Organic carbon (g kg ⁻¹)	Cation exchange capacity CEC (cmol (+) kg ⁻¹)	Limestone CaCO ₃ (g kg ⁻¹)
	Clay	Thin silt	Rough silt	Thin sand	Rough sand					
Soil-1	13.3	24.8	23.5	22.5	15.9	6.5	44.7	26	12.3	0
Soil-2	22.8	15.8	10.7	15.8	34.9	6.41	10.1	5.86	10.1	<1
Soil-3	19.5	15.4	23.6	23.8	17.7	8.39	12.5	7.2	8.88	98
Soil-4	23.9	27.3	28.1	9.8	10.9	7.9	8.7	3.8	15.85	2

2001). Each pot was 8 cm (top) in diameter and 7 cm in height with some drain holes on the bottom. Germination was assessed using three replicates of each kind of soil (spiked, aged, control) and concentration in the PM condition. The bioassay was performed in a growth chamber at 23–18 °C as the day–night temperatures. Germination was determined by visual seedling emergence (Gong et al., 2001) and recorded after 8 d in exposed seeds and controls (Vila et al., 2007). Protuberance of radicals was also taken as the initiation of germination (Chaudhuri, 2002).

After germination recording, only three seedlings of the most uniform plants were kept in each pot to perform growth assays (Gong et al., 2001). Length (root and shoot elongation), fresh and dry weight of roots and shoots and the number of leaves were measured after 17 d of growth. Shoot height was measured from the shoot base to the top of the longest leaf and root length was measured from the root–shoot junction to the top of the longest root (Liu et al., 2005). Fresh biomass was weighed immediately whereas the dry biomass was measured after oven drying (Gong et al., 2001) at 40 ± 2 °C for 72 h. Experiments were done in triplicate.

As described by Tiquia et al. (1996) and Barrena et al. (2009), phytotoxicity was then expressed by two soil contamination indicators: germination index (GI) (which involves relative seed germination) and relative root elongation (E).

$$E = (\text{Mean root length with PM} / \text{Mean root length with control}) \times 100$$

$$GI = (\text{Relative seed germination} \times E) / 100$$

With : Relative seed germination

$$= (\text{seeds germinated with PM} / \text{seeds germinated with control}) \times 100$$

The germination index was calculated by comparison to controls that were assimilated for each type of soil to a germination reference (control index: 100%).

2.4. Lead phytoavailability determination

Lead phytoavailability in the different soils (before and after ageing and in the historically polluted soil) was determined with the 0.01 M CaCl₂ extraction procedure described by Houba et al. (1996) and Uzu et al. (2009). The metal fraction extracted by CaCl₂ gives an indication of metal concentration in a soil solution and therefore of metal solubility (Meers et al., 2007). Thirty millilitres of 0.01 M CaCl₂ solution was mixed with 3 g of soil (1:10 solid solution ratio) in 50 mL polypropylene centrifugation tubes placed on a shaker table (Heidolph promax 1020) at 50 oscillations min⁻¹ for 2 h, 20 °C. After extraction, tubes were centrifuged at 10 000g for 30 min. The supernatant liquid was then filtered, acidified to 2% with distilled HNO₃ (15 M, suprapur 99.9%) and stored at 4 °C

before analysis. Extracted metal concentrations were determined by ICP-OES (IRIS Intrepid II XXDL).

2.5. Lead transfer to lettuce shoots and roots

Roots and shoots were collected 17 d after the germination test for all soil conditions. Lead (the main metal in process PM) accumulation was analysed separately for the different plant tissues after oven-drying at 40 °C for 48 h. Fresh and dried biomasses were determined. Roots and shoots were mineralised in a 1:1 mixture of HNO₃ and H₂O₂ at 80 °C for 4 h according to Uzu et al. (2009). Lead concentrations in plant samples were finally measured by ICP-OES (IRIS Intrepid II XXDL). The accuracy of acidic digestion and analytical procedures was checked using Virginia tobacco leaves (CTA-VTL-2, ICHTJ) as reference.

2.6. Microtox analysis

First used to assess acute ecotoxicity of metals in aquatic media (De Zwart and Slooff, 1983), solid-phase Microtox test is now currently used to evaluate the toxicity of contaminated soils or sediments (Rink et al., 2002; Sheehan et al., 2003; Robidoux et al., 2004; Loureiro et al., 2005; Doshi et al., 2008; Barrena et al., 2009).

The Microtox test measures the decrease in light emitted by the bioluminescent bacteria *Vibrio fischeri*. Toxicity is reported as the effective concentration EC₅₀, which is the concentration of a contaminant that produces a 50% reduction in light emission. EC₅₀ was measured after 5 and 15 min of exposure (Barrena et al., 2009). This acute test is used to determine the potential toxicity of a liquid or solid phase sample on bacteria, and by extension, toxicity on aquatic or soil microbial activity. Soil contamination can be one path for streams and groundwater contamination (Loureiro et al., 2005). Moreover, atmospheric fallout enriched in metallic particles could directly pollute surface and sub-surface waters or be transferred from the soil by infiltration or leaching processes. Therefore, the two tests (liquid and solid phases) were performed.

In view of evaluating PM toxicity in solution, the Microtox 81.9% Basic Test with the instrument MICROTOX M 500 purchased from R-biopharm (France) was used. Suspensions of industrial particles were prepared in deionised water with sodium chloride (2%) as mentioned in the manufacturer's instructions. Agitation was performed with a glass rod and 15 min on plate shaker to avoid particulate matter destruction by sonication or metal adsorption onto magnetic bars. Lyophilised bacteria were rehydrated with the included reconstitution solution just prior to performing the test (Strigul et al., 2009). Nine concentrations of PM suspensions obtained by a sequence of 1:1 dilutions ranging from 6.4 × 10⁻⁴ to 0.164 g L⁻¹ were tested.

The toxicity of various PM-spiked soil suspensions (soil-1, soil-2 and soil-3) was determined by the solid-phase test at different concentrations (Doshi et al., 2008). Three grams of PM-spiked soils at [Pb] = 1650 ± 20 mg kg⁻¹ (C₂) were dispersed in 15 mL DI, 3% NaCl. After 15 min of shaking, dilutions were made in order to test toxicity in a range from 197 to 0.048 g L⁻¹ of soil suspensions. Each

Microtox test consisted of two controls and several toxicant soil concentrations each in duplicate. Every test was performed in triplicate.

2.7. Statistical analysis

All tests were performed in triplicate and the results are presented as mean \pm SD (standard deviation). The statistical significance of values was checked using a one-way analysis of variance ANOVA with the LSD Fisher post-hoc test using the Statistica 9.0 package software. Each effect was compared to its corresponding control (with an uncontaminated soil). Statistical difference was accepted when the probability of the result assuming the null hypothesis (p) was less than 0.05.

3. Results

3.1. Phytotoxicity evaluation

PM phytotoxicity was evaluated by studying complementary parameters. Chronologically, the first observations were made on seed germination, then we report the results on root elongation and leaf growth. The results focused on the impact of: (i) PM concentrations, (ii) soil-particle interactions as a function of soil type and (iii) the effect of ageing on germination and elongation assays.

3.1.1. Effects of PM concentrations and soil-PM interactions

For germination data, a trend was observed, but it was not statistically significant. The germination index decreased when PM concentration increased (results not shown). Then, as shown in Fig. 1 (giving the relative root elongation index), root length significantly decreased when PM concentration increased (ANOVA, $p < 0.05$). A significant dose response was observed for soil-1 and soil-3.

According to Fig. 2, whatever the kind of soil, PM had an impact on shoot elongation and biomass. The development of thinner and shorter shoots was induced by PM exposure compared to controls (ANOVA, $p < 0.05$). Contrary to the root elongation results, there was not a clear dose response effect for shoots (Fig. 2). Finally, leaf number and colouration were not affected by PM (results not shown).

No significant difference was observed between the three control soils (ANOVA, $p > 0.05$): they had the same behaviour regardless of the phytotoxicity marker (germination, root and shoot growth). Nevertheless, when these soils were spiked, they ex-

Fig. 1. Influence of PM concentration and soil properties on root growing. Results are expressed as relative root elongation (% relative to controls). C₁: [Pb] = 825 \pm 15 mg kg⁻¹; C₂: [Pb] = 1650 \pm 20 mg kg⁻¹ and C₃: 2475 \pm 20 mg kg⁻¹. Values are given as mean \pm SD (standard deviation) of triplicate samples with three seedlings each.

pressed, globally, the same responses in observed effects but with different amplitude (see Figs. 1 and 2).

3.1.2. Ageing effect

In view of evaluating the soil ageing effect on PM ecotoxicity, germination and elongation tests were performed at C₂ ([Pb] = 1650 \pm 20 mg kg⁻¹) by comparison with the controls for each type of soil.

The 3 month ageing period had a significant impact on the elongation parameter. Fig. 3 shows a representation of root elongation after 17 d in the different contaminated soils, in comparison to controls. Roots grown in aged spiked soil were shorter than roots grown in non-aged spiked roots ($p < 0.05$ for soil-2 and soil-3). Actually, for the same PM concentration ([Pb] = 1650 \pm 20 mg kg⁻¹), root growth was significantly slowed down in spiked, aged soil-2 and soil-3. However, the long-term polluted soil (soil-4) was less phytotoxic; root length in this polluted soil was not significantly different to the three controls (ANOVA, Fisher test, $p > 0.05$).

Fig. 4 shows the results of lead accumulation in plant shoots (A) and roots (B) for the soil-3 ageing experiment. In fresh and aged spiked soils, lead concentrations were significantly different to controls. The ageing process on spiked soil increased lead transfer to roots and its translocation to shoots (see Fig. 4, $p < 0.05$). The same results were observed for the other studied soil-1 and soil-2 (not shown). In the long-term polluted soil, lead accumulation in roots and shoots was not as high as in spiked soils, and relatively close to control shoots. In the same way, mean lead concentrations extracted by CaCl₂ were, respectively, 4.2 \pm 0.4, 5.1 \pm 0.2 and 3.1 \pm 0.3 mg Pb kg⁻¹ of spiked soil-3, aged spiked soil-3 and long-term polluted soil.

3.2. Effects on microbial activity: bioluminescent test

3.2.1. PM suspensions: Microtox 81.9% basic test

Fig. 5 shows the results of microbial toxicity in solution. Longer exposure times were associated with lower EC₅₀, suggesting that industrial particles are toxic to microorganisms.

3.2.2. Solid-phase test and ageing effect

Table 2 summarises the EC₅₀ data for controls, spiked soils and aged spiked soils for each kind of soil suspension. All the data dealing with the effect of PM-spiked soils on bioluminescence inhibition in relation to the soil suspension concentrations (mg L⁻¹) are given in Supplemental material (Figs. S1, S2 and S3). The results were almost the same after 5 min or 15 min, so the table only reports the 5 min results. For each kind of soil, Table 2 shows that the PM-amended soils had an effect on light output at a lower concentration than the control soil (EC₅₀ obtained for a lower concentration of process PM). This representation takes into account the potential loss of luminescence due to the turbidity of soil suspensions, and the toxicity already present in soil before spiking. Soil-3 (without PM) was the most toxic, and the EC₅₀ of the control was the lowest at 12.7 g L⁻¹ of the soil suspension (equivalent to 76.2 mg L⁻¹ of PM or 20.9 mg L⁻¹ of Pb in suspensions).

Moreover, by comparison to the spiked soils with the same contamination level, ageing influenced PM toxicity (Table 2 and Supplemental material). The toxicity of soil suspensions was increased after a 3-month ageing period in the greenhouse, EC₅₀ = 169 mg L⁻¹ instead of 339 mg L⁻¹ for soil-1, EC₅₀ = 142 mg L⁻¹ instead of 689 mg L⁻¹ for soil-2 and EC₅₀ = 676 mg L⁻¹ instead of 3440 mg L⁻¹ for soil-3. The ageing effect seemed to be more important for soil-3 (and soil-2) than for soil-1 (higher difference in the EC₅₀).

Finally, the long-term polluted soil (soil-4) was tested in the Microtox assay and its EC₅₀ was determined to be EC₅₀ = 22.4 g L⁻¹

Fig. 2. Influence of PM concentration and soil properties on shoot growing: shoot length in cm (A) and fresh biomass in mg (B). C₁: [Pb] = 825 ± 15 mg kg⁻¹; C₂: [Pb] = 1650 ± 20 mg kg⁻¹ and C₃: 2475 ± 20 mg kg⁻¹. Values are given as mean ± SD (standard deviation) of triplicate samples with three seedlings each.

Fig. 3. Effect of ageing procedure on root elongation as a biomarker of PM phytotoxicity. Results are expressed according to the different soils on root length (C₂: [Pb] = 1650 ± 20 mg kg⁻¹). Values are given as mean ± SD (standard deviation) of triplicate samples with three seedlings each.

after 5 min and 20 g L⁻¹ after 15 min. These values are very close to those obtained for the control soils (the EC₅₀ was even higher than in soil-3). Therefore, the toxicity of soil-4 for *V. fischeri* was low.

4. Discussion

4.1. PM ecotoxicity assessment

PM had an impact on plant growth. Roots are in direct contact with PM during their elongation and not protected against the toxic effects of soil pollutants. Previous studies on manufactured PM concluded that they have an inhibitive effect on root elongation (Yang and Watts, 2005; Lin and Xing, 2007; Lee et al., 2008; Stampoulis et al., 2009). Process PM emitted by the lead recycling plant appears to have had a similar impact in relation to metal accumulation. Moreover, the study on lettuce shoots supported the same conclusions. Thus, shoot parameters (elongation and biomass) may be useful to compare toxicity effects after seed exposure to process particles. Nevertheless, our first results have shown that, even if a reduction trend could be described for the three soils, according to Ma et al. (2010a,b) (working on synthesised oxide nanoparticles), lettuce germination was not affected by metal soil pollution. Lin and Xing (2007) explained this phenomenon by the protection of the lettuce seed coat against external pollutant penetration, while Wierzbicka and Obidzinska (1998) attributed this to selective permeability of the seed coat. So, root elongation can be more sensitive than germination index for this type of hazardous material contamination, especially when the toxicity directly affects root development, as reported by Barrena et al. (2009).

Furthermore, process PM and PM-spiked soil suspensions had a significant impact on bacteria, as a light output decrease was observed in the Microtox test. A battery of ecotoxicological tests had already shown that synthesised thin particles are toxic to aquatic organisms, both unicellular as bacteria and animals (Nowack and Bucheli, 2007). Nevertheless, among the few studies concerning metallic PM, the conclusions strongly differ. Actually, Barrena et al. (2009) showed that thin particles of Ag, Fe or Au in suspensions did not have any effect on the bioluminescence test. In contrast, Strigul et al. (2009), working with boron nanoparticles in suspension, reported an effect on bacteria metabolism and suggested that the Microtox test is efficient for evaluating the impact of manufactured particles on water quality.

Incidentally, the ecotoxicity results on *V. fischeri* bacteria exposed to PM were coherent with the phytotoxicity results. The correlation coefficients between root length and the Microtox assay data were calculated; the R² values are, respectively, 0.92, 0.90 and 0.92 for soil-1, soil-2 and soil-3. These observations suggest that there is a clear relationship between the performed tests. Whatever ecotoxicity bioassay used, the acute toxicity of PM was highlighted, certainly due to their large surface area and composition (Ma et al., 2010a,b). Moreover, a PM dose-response effect was observed, and the Microtox and phytotoxicity tests seemed therefore to be sensitive and complementary tools for studying process PM ecotoxicity.

4.2. Impact of soil-PM interaction on bioavailability and ecotoxicity

The results of the Microtox solid-phase test are expressed as the quantity of spiked soil suspensions introduced in bacteria medium (mg of soil per litre). However, by calculating the quantity of PM added in amended soils, results could be expressed as mg of PM introduced per litre. The EC₅₀ values were, respectively, 2.2, 4.1 and 20.6 mg L⁻¹ of PM in soil-1, soil-2 and soil-3. So, there was a difference in the bacterial response between the PM suspensions (EC₅₀ = 68.7 mg L⁻¹ of PM) and the PM-amended soil suspensions. These results suggest that PM ecotoxicity was increased by soil-PM interactions. The same trend was observed by Doshi et al. (2008) working on aluminium manufactured PM. Moreover, Uzu et al. (2009) have already reported that in spiked soils, CaCl₂ metal exchangeability is ten times higher than in PM, suggesting these PM-soil interactions. Actually, according to Birkefeld et al. (2007), who studied *in situ* transformation of lead particles from a smelter in several soils, solubility is strongly dependent on soil characteristics. For example, working on organic vs. inorganic fertilisers in reducing metal phytoavailability, Singh et al. (2010) reported that organic matter contents had an impact on metal phytoavailability and transfer. However, our soils differ by several parameters such as texture, clay content, pH, lime content, organic

Fig. 4. Lead concentrations in lettuce shoots (A) and roots (B) in mg kg⁻¹ of dry weight, in different spiked or aged soils after 17 d. Results are expressed as the mean of three replicates (±SD) for a lead concentration in soils at 1650 ± 20 mg kg⁻¹.

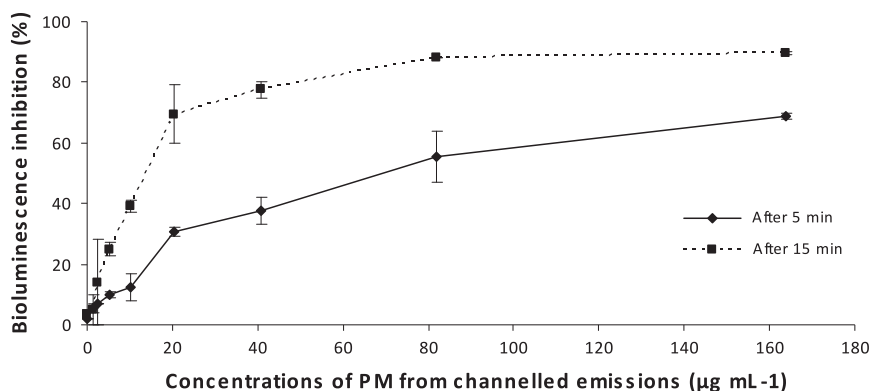

Fig. 5. Effect of PM concentrations on bioluminescent inhibition (Microtox 81.9% Basic Test).

Table 2

Effect of ageing procedure on toxicity for *Vibrio fischeri* after 5 min of contact, in relation with the kind of spiked soil. Effective concentration (EC₅₀) values are given in mg L⁻¹.

	EC ₅₀ (mg L ⁻¹) of soil suspensions		
	Controls	Spiked soils (C ₂)	Aged spiked soils (C ₂)
Soil-1	>200 000	339	169
Soil-2	38 600	689	142
Soil-3	12 700	3440	676

Notes: C₂: [Pb] = 1650 ± 20 mg kg⁻¹ impact evaluation is performed by measuring light output decrease. Toxicity is reported as effective concentration EC₅₀ for each soil suspension.

matter; the influence of even one property on soil-PM interactions is therefore too complex to highlight.

Nevertheless, the three soils do not respond in the same way according to bioluminescence inhibition. Their biogeochemistry could be an explanation. Actually, soil-3 (as a control), was characterised by a high content of limestone (98 g kg⁻¹, Table 1) and was the most toxic soil for *V. fischeri* (its EC₅₀ Control soil was the lowest). However, after spiking, it became less toxic to bacteria compared to the other PM-amended soils (its EC₅₀ Spiked soil was the highest). Thus, as already noted by Birkefeld et al. (2007), lead oxide particles incubated in calcareous sand can be covered by a crust of lead carbonate within 2 months. This crust could protect lead oxide particles against further weathering and could then decrease toxicity.

4.3. Influence of ageing on soil ecotoxicity

The results showed that the ageing period strongly influenced PM-spiked soil ecotoxicity (Figs. 3 and 4 and S1, S2 and S3). Actually, during ageing processes, metal solubilisation, availability and toxicity can be modified (Richards et al., 2000; Jalali and Khanlari, 2008; Zapusek and Lestan, 2009). Mixed with soil for several months, particle solubility could therefore have changed as suggested by the increase of lead transfer in lettuce tissues and CaCl_2 exchangeability after the ageing period, and their ecotoxicity could have been modified (Uzu et al., 2009). As shown by Lock and Janssen (2001), metal bioavailability is largely influenced by the ageing period. Moreover, as reported by Ma et al. (2010a,b), small sized particles are prone to aggregation in the aqueous phase, which may change their bioavailability and toxicity over time. PM dissolution, phase transformation and speciation are sensitive to soil geochemistry (Birkefeld et al., 2007; Uzu et al., 2009). The dissolution of particulate matter in the soil solution during the ageing processes could release several metals (as ionic compounds). Thus, this phenomenon could be an explanation of the increase in the toxicity of process particles (Fig. 3 and Supplementary materials) and lead accumulation in lettuce roots and shoots with the ageing period (Fig. 4).

However, as already noted by Lin and Xing (2008), the phytotoxicity of metallic particles cannot be explained only by the dissolution of metallic ions. The toxicity may come from ultrafine particle aggregation and adhesion on the root surface and their penetration into epidermal and cortical cells until damage is caused to the vascular cells. In the case of bacteria, the cell-PM interaction is size-dependent (Morones et al., 2005) and seems to depend also on the shape of the PM (Pal et al., 2007). For example, Nowack and Bucheli (2007) reported that nano-Ag appeared to be significantly more toxic than Ag^{2+} ions towards *Escherichia coli*. Therefore, we can suppose that ageing processes (for 3 months) combine these two effects: metallic ion dissolution in the soil solution and particle aggregation and penetration into plant tissues or bacterial cells. Toxicity was more acute in aged spiked soils. Only soil-1, characterised by its high organic matter, was not significantly more toxic after the ageing process, by comparison to the other soils (Fig. 3). Actually, several authors had previously reported this effect of organic matter on metal release, transfer and toxicity in soils (Yin et al., 2002; Inaba and Takenaka, 2005; Bermudez et al., 2010). Organic ligands could modify both metal uptake and phytotoxicity by changing free metal ion concentrations through speciation (Shahid et al., 2011).

However, the historically long-term (30 years) polluted soil was less toxic than the different spiked soils. This could be explained by long-term stabilisation processes involving strongly stabilised lead compound formation like pyromorphite and lead-enriched clay minerals (Dumat et al., 2001; Cecchi et al., 2008). Its lower toxicity and lead exchangeable fraction compared to spiked soil-1, soil-2 and soil-3 may have been due to its lower concentration of released toxicants (especially Pb). Because of long-term chemical processes, metal bioavailability in field soils decreases over time (Lock and Janssen, 2003a,b). For example, variations in the relative molecular size fractions present within the dissolved organic carbon (DOC) pool as a result of increased time and temperature may influence the proportion of element-DOC complexes and their behaviour in soils (Martínez et al., 2003). Temporal changes, climate variations and plant cultivation on metal-polluted soils could accelerate metal speciation transformations and then decrease their bioavailability (Fendorf et al., 2004; Buekers et al., 2007). Actually, by producing exudates, plants can modify metal speciation and their behaviour in soil, especially in the rhizosphere (Chaignon and Hinsinger, 2003; Uzu et al., 2009).

Thus, as reported by Lock and Janssen (2003a,b), the use of spiked soils in toxicity assays can result in an overestimation of

metal effects, especially at high pH. Therefore, the perspectives of this work could inform the testing of different ageing processes and their effect on toxicity evaluations with the root elongation assay and the Microtox test.

5. Conclusions and perspectives

This study focused on the impact of process waste metallic ultrafine particles, not intentionally emitted into the environment, on plants and microorganisms. It deals with an environmental risk assessment of contamination by atmospheric fallouts from lead recycling plants.

Due to their small size and composition, these industrial ultrafine particles are toxic for ecosystems. They reduce root and shoot elongation for plants and disturb *V. fischeri* metabolism. The ecotoxicity of these process particles was increased by short-term interactions with soils. However, after long-term exposure, ecotoxicity decreases with metal bioavailability in soils.

The interest of using combined toxicity tests (the plant elongation assay and the Microtox test) to appreciate the impact of PM on ecosystems was demonstrated. Lettuce germination was not significantly affected by metal soil pollution, suggesting that this indicator was not sensitive enough for this kind of pollutant.

Further studies could be performed in view of obtaining a range of references on the responses of ecosystems exposed to metallic particles from different sources, with different sizes and speciation, from different industrial processes, especially for the Microtox test for which there are currently only a few data available. Moreover, different ageing processes and times should be compared in view of obtaining the best simulation of stabilisation processes.

Acknowledgments

We gratefully acknowledge ADEME, the French Agency of the Environment and Energy as well as the STCM Chemical Metal Treatment Company for their technical help in experimental set-up and for their financial support.
