Abstract. Over the Mediterranean region, elevated tropospheric ozone (O₃) values are recorded, especially in summer. We use the thermal Infrared Atmospheric Sounding Interferometer (IASI) and the Weather Research and Forecasting Model with Chemistry (WRF-Chem) to understand and interpret the factors and emission sources responsible for the high O₃ concentrations observed in the Mediterranean troposphere. Six years (2008–2013) of IASI data have been analyzed and results show consistent maxima during summer, with an increase of up to 22% in the [0–8] km O₃ column in the eastern part of the basin compared to the middle of the basin. We focus on summer 2010 to investigate the processes that contribute to these summer maxima. Using two modeled O₃ tracers (inflow to the model domain and local anthropogenic emissions), we show that, between the surface and 2 km, O₃ is mostly formed from anthropogenic emissions, while above 4 km it is mostly transported from outside the domain or from stratospheric origins. Evidence of stratosphere-to-troposphere exchange (STE) events in the eastern part of the basin is shown, and corresponds to a low water vapor mixing ratio and high potential vorticity.

1 Introduction

Tropospheric ozone (O₃) is a greenhouse gas, air pollutant, and a primary source of the hydroxyl radical (OH), the most important oxidant in the atmosphere (Chameides and Walker, 1973; Crutzen, 1973). Previous observations and studies have shown that tropospheric O₃ over the Mediterranean exhibits a significant increase during summertime, especially in the east of the basin (Kouvarakis et al., 2000; Im et al., 2011; Gerasopoulos et al., 2005, 2006a; Richards et al., 2013; Zanis et al., 2014). Meteorological conditions such as frequent clear-sky conditions (Fig. 1a) and high exposure to solar radiation (Fig. 1b) in summer enhance the formation of photochemical O₃ due to the availability of its precursors. These precursors include carbon monoxide (CO), peroxy radicals generated by the photochemical oxidation of volatile organic compounds (VOCs) and nitrogen oxides (NOₓ = NO + NO₂). Locally, the eastern part of the basin is surrounded by megacities such as Cairo, Istanbul, and Athens that are large sources of local anthropogenic emissions. The geographic location of the basin makes it a receptor for anthropogenic pollution from Europe both in the boundary layer (Fig. 1c) and the mid-troposphere (Fig. 1d). The threshold O₃ value for air quality standards for the European Union (of daily maximum of running 8 h mean values of 60 ppbv) is exceeded on more than 25 days per year at a large number of stations across Europe, many of which are...
located to the south of Europe in the Mediterranean Basin (EEA, 2012). The dynamical processes of the summer circulation over the Mediterranean were previously attributed to the Hadley cell considered as the driver of the major subtropical dry zones. Rodwell and Hoskins (1996) argued that, during the June–August period, the zonal mean Hadley circulation has very little motion and cannot explain the dry season of North Africa and the Mediterranean. Rodwell and Hoskins (1996, 2001) suggested, through numerical simulations, that the Asian monsoon heating induces an equatorially trapped Rossby wave to its west that interacts with the mid-latitude westerlies, producing a region of adiabatic descent and triggering subsidence. Long-term analysis of \( \frac{dP}{dr} \) (unit: Pa s\(^{-1}\), used to represent subsidence) indeed shows a positive enhancement over the Mediterranean region (Ziv et al., 2004), making the South Asian monsoon a fundamental driver of the summer circulation over the eastern Mediterranean (Tyrlis et al., 2013). High \( \text{O}_3 \) values in the Mediterranean troposphere in the literature are attributed to different sources. Lelieveld et al. (2002) showed that, in the upper troposphere, Asian pollution is transported from the east by the monsoon across the Mediterranean tropopause into the lower stratosphere. Liu et al. (2011) showed with long-term model analysis that the dominant sources of \( \text{O}_3 \) in the Middle East (including the Mediterranean) are the transport from Asia and local production. On the other hand, Gerasopoulos et al. (2005) have shown that the mechanism that controls surface \( \text{O}_3 \) seasonal variability in the eastern basin during summer is mainly the transport from Europe. Using lidar measurements, Galani et al. (2003) detected an increase of 10% of tropospheric \( \text{O}_3 \) between 4.5 and 6.5 km due to stratosphere-to-troposphere exchange (STE) events. Zbinden et al. (2013), using aircraft data from the MOZAIC (Measurements of OZone and water vapour by in-service Airbus airCraft) program over 15 years (1994–2009), showed that the tropospheric \( \text{O}_3 \) columns in the east of the Mediterranean reached a maximum of 43.2 DU (Dobson units) during June–July. This recorded maximum exceeds the maximum recorded for Beijing for the same period, for example. Model calculation using WRF-Chem (Weather Research and Forecasting model coupled with Chemistry) and EMEP (European Monitoring and Evaluation Programme) MSC-W (Meteorological Synthesizing Centre – West) models of the eastern Mediterranean during heat waves in 2007 showed that the daily maximum near-surface \( \text{O}_3 \) is mostly sensitive to anthropogenic emissions of \( \text{O}_3 \) precursors (Hodnebrog et al., 2012). Im et al. (2011) found that the near-surface ozone mixing ratios increase almost linearly with temperature by 1.0±0.1 ppb \( \text{O}_3 \) per kelvin. STE processes can affect the tropospheric \( \text{O}_3 \) budget and impact air quality if transported to the boundary layer (Fiore et al., 2002). Stratospheric intrusions have been detected in the Mediterranean region, especially on the eastern side (Galani et al., 2003; Zanis et al., 2014), because it lies to the south of the Northern Hemisphere polar jet flowing over midlatitudes (Stohl et al., 2000; Gerasopoulos et al., 2001). Understanding the factors that contribute to the \( \text{O}_3 \) maxima is important for developing control measures and preventing pollution buildup. In this study we analyze \( \text{O}_3 \) and its sources at different altitudes in the Mediterranean troposphere. Section 2 introduces the model and observations data sets used in this study. In Sect. 3, we analyze 6 years (2008–2013) of Infrared Atmospheric Sounding Interferometer (IASI) tropospheric \([0–8]\) km \( \text{O}_3 \) column seasonal variation above the whole Mediterranean Basin as well as at 15 and 30° E, representative of what we henceforth refer to as “middle of the basin” and “east of the basin” respectively. In Sect. 4 we focus on summer 2010, as an example year, and validate the WRF-Chem model simulation with surface \( \text{O}_3 \) and IASI data, and then use the WRF-Chem model to assess the sources of \( \text{O}_3 \) in the troposphere. In Sect. 5, we use IASI and WRF-Chem free-tropospheric \( \text{O}_3 \) data to investigate potential STE events. Discussion and conclusions are given in Sect. 6.

2 Model and observational data

2.1 WRF-Chem model

In this study, we use the regional chemistry transport model WRF-Chem, version 3.2 (Grell et al., 2005), to assess the budget and spatiotemporal variability of \( \text{O}_3 \) over the Mediterranean during summer 2010. The model domain shown in Fig. 2a is over Europe and the Mediterranean Basin, the latter being the focus of this study (Fig. 2b). The horizontal resolution is of 50 km × 50 km and the vertical resolution is of 28 levels between the surface and 10 hPa. The...
meteorological initial and boundary conditions are based on
the National Centers for Environmental Prediction (NCEP)
Final (FNL) analyses with analysis nudging for wind, tem-
perature, and humidity applied. Fields are provided every
6 h with 1° horizontal resolution and 27 vertical levels from
the surface up to 10 hPa. The chemical initial and bound-
ary conditions, spatially and temporally varying (6 h), are
constrained by global chemical transport simulations from
MOZART-4/GEOS-5 with 1.9° × 2.5° horizontal resolution
(Emmons et al., 2010a). The WRF-Chem gas-phase chemical
mechanism is that from Model for Ozone and Related Chem-
ical Tracers, version 4 (MOZART-4) (Emmons et al., 2010a),
which is coupled to the aerosol scheme Goddard Chemistry
Aerosol Radiation and Transport (GOCART) model (Chin
et al., 2002). The model also includes anthropogenic and
fire emissions that are calculated offline. The anthropogenic
emissions used within the WRF-Chem model were de-
veloped within the context of the ECLIPSE European project
using the Greenhouse gas and Air pollution Interactions and
Synergies (GAINS) model. In addition to the ECLIPSE V4.0
anthropogenic emissions, ship emissions from the RCP 6.0
scenario (Fujino et al., 2006; Hijioka et al., 2008) were used.
Biomass burning emissions are obtained from the Fire In-
ventory from NCAR (FINN V1) (Wiedinmyer et al., 2011).
Biogenic emissions are calculated online from the Model of
Emissions of Gases and Aerosols from Nature (MEGAN)
(Guenther et al., 2006). The WRF-Chem simulation outputs
are saved every 2 h from 1 June until 31 August 2010.
In this study, we use a tagging method for O₃ (Emmons
et al., 2012), which has been applied in global models for
diagnosing contributions for individual sources to O₃ (e.g.,
Lamarque et al., 2005; Pfister et al., 2006, 2008; Emmons
et al., 2010b; Wespes et al., 2012), as well as in other global
and regional chemical transport models (Ma et al., 2002; Hess
and Zbinden, 2013). Recently, this scheme was used for the
first time in the WRF-Chem model to quantify the contri-
bution of transport on surface O₃ over California (Pfister
et al., 2013). Here, we apply this scheme to keep track of the
contribution of O₃ within the WRF-Chem domain. To de-
determine O₃ sources, tagged NOₓ is traced through the odd
nitrogen species (e.g., PAN, HNO₃, organic nitrates) to ac-
count for NOₓ recycling (Emmons et al., 2012). Two separate
tracer runs were conducted with the same emissions and ini-
tial and boundary conditions. In the first one, the O₃-ANTHRO
tracer accounts for the anthropogenic regional tagged NOₓ,
while the second one, the O₃-INFLOW tracer, accounts for
tagged O₃ as well as all nitrogen species at the lateral bound-
aries of the regional model domain. The O₃-INFLOW tracer
includes O₃ and O₁ precursors from all natural (including
lightning and stratospheric O₁) and anthropogenic sources
outside the regional modeling domain. Within the regional
modeling domain, O₃-INFLOW undergoes transport and chem-
ical processes but is not produced from sources other than
from reactions including the tagged species. Since the strato-
spheric O₃ is controlled by the lateral boundaries in this ver-
ion of WRF-Chem, O₃ from stratospheric intrusions within
the regional domain would be labeled as O₃-INFLOW as well.
More details about the tagging scheme are provided in Em-
mons et al. (2012). Two more tracers are available to com-
plete the O₃ budget: O₃ from biogenic sources and O₃ from
fires. Given that their contribution to the total budget in com-
parison with the O₃-INFLOW and O₃-ANTHRO tracers is small
(< 10 %), they are analyzed together in this study as “resid-
uals” to the total budget and their contribution is defined as
100 % − (O₃-ANTHRO % + O₃-INFLOW %). We focus our anal-
ysis on summer 2010, which corresponds to the year of the
anthropogenic emission inventory used in the model. Dur-
ing July–August 2010, a heat wave occurred in Russia that
caused severe fires with high O₃ and O₁ precursor emissions
that were probably transported to the Mediterranean region;
this will be further investigated in this study.

2.2 EMEP data

The EMEP (European Monitoring and Evaluation Pro-
gramme) O₃ hourly data (http://ebas.nilu.no/) are used to val-
idate the WRF-Chem model at the surface. All ozone mea-
urements within EMEP are done with UV monitors. In this
study, measurements at eight ground rural background sites
during the summer of 2010 are used. Details on the EMEP
observation system can be found in Hjellbrekke et al. (2012).
The geographic locations of the eight stations used for vali-
dation are plotted in Fig. 2, and the corresponding details are
listed in Table 1. Two more station data sets were available,
GR01-Aliartos (38.37° N, 23.11° E) and IT01-Montelibretti
(42.1° N, 12.63° E), for the same period. We disregarded the
data from these stations because they show a strong diurnal
variation of 80–90 ppbv amplitude and recurrent near-zero
O₃ concentrations throughout the period of the study, and
were thus considered unreliable.

Figure 3. Random O$_3$ averaging kernels over the Mediterranean: the functions are for the [surface–3], [4–6], [6–9], and [10–12] km partial columns characterizing a retrieval for an observation chosen randomly above land (Greece, left panel) and above the sea (right panel) during June 2010.

2.3 IASI satellite measurements

The MetOp satellites, launched in October 2006 and September 2012, each carry an IASI instrument, which have been operationally sounding the atmosphere since June 2007 (IASI-1) and January 2013 (IASI-2). The IASI instruments are nadir-looking Fourier transform spectrometers that probe the Earth’s atmosphere in the thermal infrared spectral range between 645 and 2760 cm$^{-1}$, with a spectral resolution of 0.5 cm$^{-1}$ (apodized) and 0.25 cm$^{-1}$ spectral sampling. Global distributions of O$_3$ vertical profiles are retrieved in near-real time using a dedicated radiative transfer and retrieval software for the IASI O$_3$ product, the Fast Optimal Retrievals on Layers for IASI (FORLI-O$_3$) (Hurtmans et al., 2012). The IASI FORLI-O$_3$ observations are selected for scenes with cloud coverage below 13% and with root mean square (rms) of the spectral fit residual lower than 3.5 x 10$^{-8}$ W cm$^{-2}$ sr cm$^{-1}$. Details about the chemical components that can be measured by IASI can be found in Clerbaux et al. (2009), Coheur et al. (2009), Turquety et al. (2009), and Clarisse et al. (2011). IASI has the highest O$_3$ sensitivity in the mid- to upper troposphere (Safieddine et al., 2013). Figure 3 shows the partial column averaging kernel function for two specific observations above land and sea during June 2010. It can be seen that the sensitivity to the O$_3$ profile is maximal around 4–10 km for both observations. IASI sensitivity near the surface is usually limited above the sea, as seen on the right panel of Fig. 3, and better over land, as seen in the left panel, and with corresponding better thermal contrast (7.8° above land, and 1.2° above sea). IASI is able to detect several pollutants (e.g., carbon monoxide, ammonia, sulfur dioxide, and ammonium sulfate aerosols), especially when a large thermal contrast is combined with stable meteorological conditions, leading to the accumulation of pollutants near the surface (Boynard et al., 2014).

3 Tropospheric O$_3$ seasonal variation as seen by IASI

To investigate the seasonal behavior of tropospheric O$_3$ above the Mediterranean, in Fig. 4 we plot the [0–8] km partial tropospheric O$_3$ column as seen by IASI during the period of 2008 to 2013. The data were averaged seasonally, and daytime observations were used since the information content of IASI O$_3$ data is shown to be higher during the day (Clerbaux et al., 2009). We observe a similar tropospheric O$_3$ seasonal behavior each year. The weakest values are observed in winter (DJF) and autumn (SON), when solar activity is minimal. Increasing values in spring (MAM) are due to the increase in O$_3$ production from photochemistry, buildup of winter O$_3$ and its precursors, transport, and/or from O$_3$ of stratospheric origin integrating into the troposphere. The [0–8] km column reaches a maximum in summer (JJA) due to high photochemical O$_3$ production, horizontal transport into the region, or STE, all of which will be investigated in detail in the following sections. Richards et al. (2013) detected a similar spatial distribution with the Global Ozone Monitoring Experiment-2 (GOME-2) during the summers of 2007 and 2008, with values exceeding 32 DU at the east of the...
Figure 4. Six-year seasonal variation of [0–8] km integrated IASI O\textsubscript{3} column over the Mediterranean region for winter, spring, summer, and autumn. White pixels correspond to a filter applied to poor spectral fits because of emissivity issues in the FORLI radiative transfer above the Sahara.

Figure 5. Six-year monthly variation of the integrated [0–8] km IASI O\textsubscript{3} column averaged over [30–45\degree N] at 15\degree E (in black) and 30\degree E (in red). Higher summer values are observed to the east of the basin at 30\degree E.

Figure 5 shows that, during the period of 2008 to 2013, the summers in the east of the basin, notably at 30\degree E (plotted in red), are marked by elevated tropospheric [0–8] km O\textsubscript{3} values. The difference between the two O\textsubscript{3} columns at the 2 different longitudes was highest (4.7 DU – 22 \%) during June 2012. The highest recorded values were up to 30DU in July 2010 at 30\degree E. This period coincides with the 2010 Russian heat wave (Schubert et al., 2011), which caused severe fires with high O\textsubscript{3} precursors emissions (R’Honi et al., 2013). Further discussion is provided in Sect. 4.2.

4 O\textsubscript{3} budget from the WRF-Chem model during summer 2010

From this section onwards, we focus our analysis on summer 2010, the year of the anthropogenic emission inventory used in the model. We evaluate the model then we discuss the O\textsubscript{3} budget at different altitude levels in the Mediterranean troposphere.

4.1 Model evaluation: comparison to EMEP and IASI

The model is evaluated by comparing O\textsubscript{3} concentrations with ground O\textsubscript{3} data from the EMEP stations (Sect. 2.2) and then free-tropospheric O\textsubscript{3} data from IASI (Sect. 2.3).
Linear spatial interpolation was applied to WRF-Chem data in order to correlate the model outputs and the EMEP data that were averaged every 2 h to coincide with the model run output data. Figure 6 shows the individual time series of the data of the eight stations used for the validation. Table 2 shows the individual O$_3$ correlation and bias between WRF-Chem and the EMEP for each of the stations used in this study during JJA 2010. The model simulates the surface O$_3$ with a correlation ranging from 0.41 (ES06) to 0.80 (ES12) and a mean value of 0.52. Figure 6 and Table 2 show that the model reasonably well reproduces the average amplitude of the daily cycle seen in the observation. For all stations except ES06 and ES10, the model underestimates the ground observation during the summer period with a mean relative error between $-23.9$ and $-6.4\%$. The biases reported may be due to the resolution of the model resulting in a grid of around 50 km around the EMEP rural sites that may include other surface O$_3$ contributions. Other possible reasons include difficulties in simulating local flow patterns due to topography and land–sea circulation, as well as uncertainties in emissions and NO$_x$ concentrations (Pfister et al., 2013). Our results compare well with the study by Tuccella et al. (2012), which compared WRF-Chem to 75 EMEP stations over Europe during 2007 and found that hourly O$_3$ exhibits a correlation with observations ranging from 0.38 to 0.83. The largest discrepancy observed, with modeled O$_3$ values larger than 80 ppbv, is for the station ES06-Mahon (39.87$^\circ$ N, 4.32$^\circ$ E), which might be due to a particular uncertainty in the model emissions or dry deposition over this area.

### 4.1.2 Comparison to IASI observations

Averaged data for summer 2010 are used for the comparison of WRF-Chem and IASI O$_3$ [4–10] km free-tropospheric column. The modeled profile is first linearly interpolated to the time and location of the retrieval. Then, the averaging kernels associated with each IASI measurement and its a priori profile are applied to the interpolated modeled profile (of around seven layers between 4 and 10 km). Figure 7 shows
the spatial distribution of the [4–10] km integrated IASI and WRF-Chem model \( \text{O}_3 \) column along with the relative differences. We chose to analyze this part of the atmosphere in particular because IASI has a better sensitivity between 4 and 10 km over both land and water as shown in Fig. 3. The model reproduces the spatial patterns seen by IASI during summer (JJA) 2010 well, with a correlation coefficient of about 0.93 and a summertime mean bias of 6.1 DU (25 %) (not shown). The model underestimation of the [4–10] km \( \text{O}_3 \) column might due to the difficulties in resolving the high \( \text{O}_3 \) concentrations observed in transported plumes over large distances (Pfister et al., 2013). On the other hand, the high discrepancies seen over northern Africa might be due to poor spectral fits from IASI above surfaces with sharp emissivity variations, particularly above the desert (Hurtmans et al., 2012), leading to a possible overestimation of the real profile. We analyzed the IASI total retrieval error for the [4–10] km partial column (not shown here) and found that it is on average around 7 % in the model domain, and between 7 and 12 % where the discrepancies between the model and IASI are the highest.

4.2 Origins of boundary layer \( \text{O}_3 \) over the Mediterranean

Modeled \( \text{O}_3 \) concentrations are illustrated in Fig. 8a–c at the surface and 1 and 2 km during JJA 2010. At the surface, modeled \( \text{O}_3 \) exhibits the highest values downwind from the European continent. At 1 and 2 km the whole eastern part of the basin is characterized by high \( \text{O}_3 \) mixing ratios. In
order to investigate possible sources of high \( \text{O}_3 \), we run the model with two different tracers of pollution, \( \text{O}_3\text{-ANTHRO} \) and \( \text{O}_3\text{-INFLOW} \), as described in Sect. 2.1. \( \text{O}_3\text{-ANTHRO} \) (Fig. 8d–f) assesses the possible anthropogenic contribution of \( \text{O}_3 \) at different altitudes, while \( \text{O}_3\text{-INFLOW} \) (Fig. 8g–i) provides an estimate of transport of \( \text{O}_3 \), including the stratosphere. The residual plots plotted in panels j–l show the completion of the \( \text{O}_3 \) budget, and represent the \( \text{O}_3 \) contribution from fires and biogenic sources. These plots show that the residual contribution is between 0 and 10 %, inferring that \( \text{O}_3\text{-ANTHRO} \) and \( \text{O}_3\text{-INFLOW} \) combined are responsible for 90 to 100 % of the total \( \text{O}_3 \) budget over the model domain at the different altitudes of Fig. 8. The surface shows a high contribution from the anthropogenic emission tracer (\( \text{O}_3\text{-ANTHRO} > 85 \) %), with almost zero contribution from the inflow tracer. This shows the importance of local emissions to the \( \text{O}_3 \) surface concentration. At 1 km, the highest contribution is also for the anthropogenic tracer (up to 75–80 %), whereas the result is mixed at 2 km between the two tracers (around 50–60 % for \( \text{O}_3\text{-ANTHRO} \) and 40–50 % for \( \text{O}_3\text{-INFLOW} \)), suggesting that up to 50 % of the \( \text{O}_3 \) available at 2 km is being transported. The rest of the \( \text{O}_3 \) plotted in the residual plots (panels j–l) and decreasing with altitude is suggested to be from fire sources, as the extended domain (Fig. 2a) used in the study includes parts of the region hit by the Russian fires of summer 2010.

4.3 Origins of free-tropospheric \( \text{O}_3 \) over the Mediterranean

\( \text{O}_3 \) concentrations at 4, 6, and 8 km in Fig. 9a–c show that the eastern part of the basin is subject to much higher \( \text{O}_3 \) values, reaching up to 100 ppbv between 6 and 8 km (see further discussion in Sect. 5). The anthropogenic contribution decreases with altitude, whereas the \( \text{O}_3 \) inflow contribution increases. The northeastern corner of the modeled domain in panels d–f show anthropogenic contribution between 20 and 40 %. This might be due to important vertical transport and mixing in the free troposphere. These values can be correlated with the \( \text{O}_3 \) residuals plotted in panels j–l. These panels show an \( \text{O}_3 \) signature in the north eastern corner of the domain. This signature is probably related to the emitted \( \text{O}_3 \) precursors from fires sources in the model domain (Fig. 2) and lifted to the upper troposphere due to convective movements during the Russian fires of summer 2010. We can also suppose that certain anthropogenic \( \text{O}_3 \) precursors, like \( \text{NO}_x \), near the fire sources were also transported with the same convective movements to the same part of the domain and eventually contributed to the production of anthropogenic \( \text{O}_3 \) in that region. Panels g–i show that 70 to 100 % of the available \( \text{O}_3 \) between 4 and 8 km does not come from local sources. The high values are likely due to long-range transport of pollution from outside the study region or transport of air masses from the stratosphere, which we will discuss in the following section. The low values recorded in the residual plots in panels j–l show that the \( \text{O}_3 \) budget in the free troposphere over this region is controlled almost exclusively by local anthropogenic sources and transport.
5 WRF-Chem and IASI detection of STE events

Figures 4 and 5 and Fig. 9a–c showed that the eastern part of the Mediterranean Basin in summer is subject to high O$_3$ mixing ratios at 4, 6, and 8 km. In order to further investigate the sources and processes responsible for these enhancements, modeled and observed IASI O$_3$ vertical profiles in the troposphere were examined, during summer 2010, to try to detect possible STE events.

Figure 10 shows the tropospheric O$_3$ vertical distributions along 15°E (mid-Mediterranean) and 30°E (eastern Mediterranean) for IASI (panels a and b) and WRF-Chem, smoothed with the IASI averaging kernels (panels c and d) for JJA 2010. Between 4 and 8 km, panels b and d show higher values of O$_3$ in the eastern part of the basin (30°E), with concentrations ranging between 50 and 100 ppbv for IASI and 40 to 100 ppbv for WRF-Chem (WRF-Chem underestimates IASI as shown in Fig. 7).

Since stratospheric intrusions within the regional domain are included in the O$_3$-INFLOW tracer, it is useful to use other stratospheric tracers to distinguish the transport from the stratosphere. The potential vorticity (PV) and the water vapor mixing ratio ($Q_{vap}$) measurements can be used as markers of transport from the upper troposphere–lower stratosphere (UTLS) to the troposphere: elevated O$_3$ and PV, as well as low $Q_{vap}$ values, would indicate that high freetropospheric values are due to downward transport from the UTLS (Holton et al., 1995). Here, we study PV and $Q_{vap}$ at 4, 6, 8, and 10 km calculated from the WRF-Chem model run parameters. Figure 11 shows that, starting at 4 km, higher PV and lower $Q_{vap}$ values start to develop to the east of the basin. At 8 and 10 km, the highest PV values (1.5 to 2 potential vorticity units [puv]); 1 puv = $10^{-6}$ m$^2$ K kg$^{-1}$ s$^{-1}$) and the lowest $Q_{vap}$ values (0–0.10 g kg$^{-1}$) are recorded to the east of the basin, in comparison with low PV values in the middle and to the west of the basin (0.5–1) with high $Q_{vap}$ values (0.1–0.15). The high PV/low $Q_{vap}$ values to the east are in accordance with Figs. 9 and 10, strongly suggesting that this part of the basin is subject to transport from the UTLS into the free troposphere. In fact, at 30°E and around 37–39° N (panels b and d of Fig. 10), both IASI and the model suggest a stratospheric intrusion. This intrusion corresponds to PV values between 1.4 and 2 puv at 8 km and $Q_{vap}$ values around 0.05 g kg$^{-1}$. In a recent study, Zanis et al. (2014), using a 12-year climatology (1998–2009) of the ERA-interim reanalysis, also detected frequent events of STE with PV ranging between 0.4 and 1.4 puv and specific humidity values between 0.01 and 2 g kg$^{-1}$ between 700 and 250 hPa during July and August to the east of the basin, in accordance with our results for summer 2010 at 4, 6, and 8 km.

6 Discussion and conclusions

Six years of tropospheric O$_3$ observations provided by the IASI mission above the Mediterranean are shown. Tropospheric [0–8] km O$_3$ columns show a consistent seasonal behavior over the period 2008–2013, with pronounced maxima in summer and with higher values to the east of the basin. A complementary study by Doche et al. (2014) using IASI data at 3 km height also showed 6-year recurrent O$_3$ summer maxima in July to the east of the basin. Since IASI has a lower sensitivity in the lower troposphere and above the sea, the anthropogenic emission contribution to the boundary layer O$_3$ is not well captured by the instrument. However, IASI is able to detect high tropospheric O$_3$ values in the free to upper troposphere, where its sensitivity is the highest, to the east of the basin during the 6 years. Focusing on summer 2010, we use IASI and the regional chemical transport model WRF-Chem to interpret these maxima. A tagging scheme is used to keep track of O$_3$ from anthropogenic sources in the domain (O$_3$-ANTHRPO) and O$_3$ from inflow at the domain boundaries and stratosphere (O$_3$-INFLOW). Our results show that transport plays an essential role in the O$_3$ budget over the Mediterranean troposphere and that summer O$_3$ maxima over the region are especially recorded in the eastern part of the basin. Even though high local anthropogenic emissions are responsible for 60–100% of O$_3$ in the boundary layer (surface–2 km), as demonstrated by the anthropogenic O$_3$ tracer of the WRF-Chem model, O$_3$ is mainly transported above 2 km. Kalabokas et al. (2007, 2013) showed that the highest ozone concentrations in the lower troposphere are associated with large-scale subsidence of ozone-rich air masses from the upper troposphere. However, Zanis et al. (2014), using model simulations, reported that long-distance transport and local
Photochemical processes dominate at the low troposphere. In this study and in the free troposphere, WRF-Chem shows that vertical and lateral transport of O$_3$ (represented by the O$_3$-INFLOW tracer) is responsible for 70–100% of O$_3$ at 4, 6, and 8 km. In the eastern Mediterranean, Roelofs et al. (2003) showed important contributions to elevated O$_3$ in the middle troposphere by transport from the stratosphere. More recently, Hess and Zbinden (2013) showed that stratospheric interannual O$_3$ variability significantly drives the O$_3$ variability in the middle troposphere between 30 and 90° N, but not the overall trend, which is largely affected by transport processes. The increase in O$_3$ seen by the model and the IASI instrument in the eastern part of the Mediterranean Basin suggests that stratosphere-to-troposphere exchange (STE) events contribute to elevated ozone in the upper free troposphere.

This is further shown in the WRF-Chem simulations that predict elevated potential vorticity (PV) and water vapor mixing ratio ($Q_{vap}$) over the same region. This result is in agreement with many previous studies (e.g., Butkovic et al., 1990; Kalabokas and Bartzis, 1998; Kalabokas et al., 2000, 2007; Kouvarakis et al., 2000; Lelieveld et al., 2002; Sprenger and Wernli, 2003; Papayannis et al., 2005; Gerasopoulos et al., 2006b; Akritidis et al., 2010; Zanis et al., 2014; Doche et al., 2014) that have shown the occurrence of STE events in the eastern Mediterranean region in summer. Since O$_3$ maxima have the potential to strongly impact regional air quality and climate (e.g., Hauglustaine and Brasseur, 2001), the present study further demonstrates the importance of quantifying and analyzing O$_3$ and its sources at different altitudes in the atmosphere. Quantification of long-term trends and distinguishing between the different sources are crucial. This should be possible with observations and model runs over longer timescales with additional tracers to identify all O$_3$ sources.

Acknowledgements. IASI is a joint mission of EUMETSAT and the Centre National d’Etudes Spatiales (CNES, France). The IASI L1 data are distributed in near-real time by EUMETSAT through the EumetCast distribution system. The authors acknowledge the French Ether atmospheric database administrators (www.pole-ether.fr) for providing the IASI L1C data and L2 temperature data. This work was undertaken under the auspices of the O3M-SAF project of the EUMETSAT and supported by the European Space Agency (ozone CCI project). The French scientists are grateful to CNES and Centre National de la Recherche Scientifique (CNRS) for financial support. The research in Belgium is funded by the Belgian State Federal Office for Scientific, Technical and Cultural Affairs and the European Space Agency (ESA Prodex arrangement). P. F. Coheur is a senior research associate with F.R.S-FNRS. Support is also acknowledged from the EU FP7 ECLIPSE (Evaluating the Climate and Air Quality Impacts of Short-Lived Pollutants) project (no. 282688).
