June 16, 2014

Abstract
We study the existence of different notions of values in two-person zero-sum repeated games where the state evolves and players receive signals. We provide some examples showing that the limsup value and the uniform value may not exist in general. Then, we show the existence of the value for any Borel payoff function if the players observe a public signal including the actions played. We prove also two other positive results without assumptions on the signaling structure: the existence of the sup-value and the existence of the uniform value in recursive games with non-negative payoffs.

1 Introduction
The aim of this article is to study two-player zero-sum general repeated games with signals (sometimes called “stochastic games with partial observation”). At each stage, both players choose some actions. This generates a stage payoff then a new state and new signals are randomly chosen according to a transition function. Shapley [23] studied the special case of stochastic games where the players observe, at each stage, the current state and the past actions.

There are several ways to analyze these games. In this article, we will first use a point of view coming from the literature of “game determinacy” (Gale and Stewart [3]). One defines an evaluation on the set of infinite histories and then study the existence of the value in the normal form game. Several evaluations will be considered.

In the initial model of Gale and Stewart [3] of two-person zero-sum dynamic game with perfect information, there is no state variable. The players choose, one after the other, an action from a finite set and both observe the previous choices. Given a subset \( A \) of the set of plays (infinite sequences of actions), player 1 wins if and only if the actual play belongs to the set \( A \): the payoff function is the indicator function of \( A \). Gale and Stewart proved that the game is determined: either player 1 has a winning strategy or player 2 has a winning strategy, if \( A \) is open or closed with respect to the product topology. This result was then extended to more and more general classes of sets until Martin [13] proved the determinacy for every Borel...
set. When $A$ is an arbitrary subset of plays, Gale and Stewart [3] showed that the game may be not determined.

In 1969, Blackwell [1] introduced a model where the players play simultaneously (and are still told their choices). Due to the lag of information, the determinacy problem is not well defined. Instead, one investigates the probability that the play belongs to $A$. When $A$ is a $G_{\delta}$-set, a countable intersection of open sets, Blackwell proved that there exists a real number $v$, the value of the game, such that for each $\varepsilon > 0$, player 1 can ensure that the probability to be in $A$ is greater than $v - \varepsilon$, whereas player 2 can ensure that the probability is less than $v + \varepsilon$. Following this literature of determinacy, Maitra and Sudderth studied stochastic games (in the framework of Shapley’s model) and the largest payoff obtained infinitely often. They prove the existence of a value, called limsup value, in the countable framework [8], in the Borelian framework [9] and in a finitely additive setting [10]. In the two first cases, they assume some finiteness assumption at least on the action space on one side. Their result especially applies to finite stochastic games where the payoff is the limsup of the mean expected payoff.

The result of Blackwell was extended by Martin [14] to any Borel-measurable evaluation function defined on the set of plays, whereas Maitra and Sudderth [11] extended to Borel-measurable evaluation function their own result in the finitely additive setting. In all these results, the players observe past actions and the current state.

Another notion used in the study of stochastic games (where a play generates a sequence of stage payoffs) is the uniform value where some uniformity condition is required. Basically one looks at the largest amount that can be obtained by a given strategy for a family of evaluations (corresponding to longer and longer games). There are examples where the uniform value does not exist: Lehrer and Sorin [7] describe such a game with a countable set of states and only one player having a finite action set. On the other hand, Rosenberg, Solan and Vieille [20] proved the existence of the uniform value in partial observation Markov Decision Processes (one player) when the set of states and the set of actions are finite. This result was extended by Renault [18] to general action space.

The case of stochastic games with standard signaling, i.e. where the players observes the state and the actions played has been solved by Mertens and Neyman [16]. They proved the existence of a uniform value for games with a finite set of state and finite sets of actions. In fact, their proof also shows the existence of a value for the limsup of the mean payoff, as studied in Maitra and Sudderth and that both values are equal.

The aim of this paper is to provide new existence results when the players are observing only signals on state and actions. In Section 2, we define the model and present several specific Borel evaluations. We prove the existence of a value in games where the evaluation of a play is the largest stage payoff obtained along it, called $\sup$ evaluation and study several examples where the limsup value does not exist. Section 3 is the core of this paper. We focus on the case of symmetric signaling structure: repeated games where both players have the same information at each stage, and prove that a value exists for any Borel evaluation. For the proof, we introduce an auxiliary problem where the player observes the state and the actions played and we apply the generalization of Martin’s result to (standard) stochastic games. Finally, in Section 4, we introduce formally the notion of uniform value and prove its existence in recursive game with non-negative payoff.

2 Repeated game with signals and Borel evaluation

Given a set $X$, we denote by $\Delta_f(X)$ the set of probabilities with finite support on $X$. For any element $x \in X$, $\delta_x$ stands for the Dirac measure concentrated on $x$. 

=model

2
2.1 Model

A repeated game form with signals \( \Gamma = (X, I, J, C, D, \pi, q) \) is defined by a countable set of states \( X \), two finite sets of actions \( I \) and \( J \), two finite sets of signals \( C \) and \( D \), an initial distribution \( \pi \in \Delta_f(X \times C \times D) \) and a transition function \( q \) from \( X \times I \times J \) to \( \Delta_f(X \times C \times D) \). A repeated game with signals \((\Gamma, g)\) is a pair of a repeated game form and a stage payoff function \( g \) from \( X \times I \times J \) to \([0, 1]\).

This corresponds to the general model of repeated game introduced in Mertens, Sorin and Zamir [15].

The game is played as follows. First, a triple \((x_1, c_1, d_1)\) is drawn according to the probability \(\pi\). The initial state is \(x_1\), player 1 learns \(c_1\) whereas player 2 learns \(d_1\). Then, independently, player 1 chooses an action \(i_1\) in \(I\) and player 2 chooses an action \(j_1\) in \(J\). A new triple \((x_2, c_2, d_2)\) is drawn according to the probability distribution \(q(x_1, i_1, j_1)\), the new state is \(x_2\), player 1 learns \(c_2\), player 2 learns \(d_2\) and so on. At each stage \(n\) players choose actions \(i_n\) and \(j_n\) and a triple \((c_{n+1}, d_{n+1}, x_{n+1})\) is drawn according to \(q(x_n, i_n, j_n)\), where \(x_n\) is the current state, inducing the signals received by the players and the state at the next stage.

For each \(n \geq 1\), we denote by \(H_n = (X \times C \times D \times I \times J)^{n-1} \times X \times C \times D\) the set of finite histories of length \(n\), by \(H^\infty_n = (C \times I)^{n-1} \times C\) the set of histories of length \(n\) for player 1 and by \(H^\infty_n = (D \times J)^{n-1} \times D\) the set of histories of length \(n\) for player 2. Let \(H = \bigcup_{n \geq 1} H_n\).

Assuming perfect recall, a behavioral strategy for player 1 is a sequence \(\sigma = (\sigma_n)_{n \geq 1}\), where \(\sigma_n\), the strategy at stage \(n\), is a mapping from \(H^\infty_n\) to \(\Delta(I)\), with the interpretation that \(\sigma_n(h)\) is the lottery on actions used by player 1 after \(h \in H^\infty_n\). In particular, the strategy \(\sigma_1\) at stage 1 is simply a mapping from \(C\) to \(\Delta(I)\) giving the law of the first action played by player 1 as a function of his initial signal. Similarly, a behavioral strategy for player 2 is a sequence \(\tau = (\tau_n)_{n \geq 1}\), where \(\tau_n\) is a mapping from \(H^\infty_n\) to \(\Delta(J)\). We denote by \(\Sigma\) and \(\mathcal{T}\) the sets of behavioral strategies of player 1 and player 2, respectively.

If for every \(n \geq 1\) and \(h \in H^\infty_n\), \(\sigma_n(h)\) is a Dirac measure then the strategy is pure. A mixed strategy is a distribution over pure strategies.

No additional measurability assumptions on the strategies are needed since the set of states is countable and the sets of actions and signals are finite. It is standard that a pair of strategies \((\sigma, \tau)\) induce a probability \(\mathbb{P}_{\sigma, \tau}\) on the set of plays \(H_\infty = (X \times C \times D \times I \times J)^\infty\) endowed with the \(\sigma\)-algebra \(\mathcal{H}_\infty\) generated by the cylinders above the elements of \(H\). We denote by \(\mathbb{E}_{\sigma, \tau}\) the corresponding expectation.

Note also that since the initial distribution \(\pi\) has finite support and the sets of actions are finite, there exists a finite subset \(H^\infty_0 \subset H_n\) such that for all strategies \((\sigma, \tau)\) the set of histories that are reached at stage \(n\) with a positive probability is included \(H^\infty_0\).

Historically, the first models of repeated games assumed that both \(c_{n+1}\) and \(d_{n+1}\) contain \((i_n, j_n)\) (standard signalling on the moves also called “full monitoring”). A stochastic game corresponds to the case where the state is known: both \(c_{n+1}\) and \(d_{n+1}\) contain \(x_{n+1}\).

A game with incomplete information corresponds to the case where the state is fixed: \(x_1 = x_n, \forall n\), but not necessarily known by the players.

Several extensions have been proposed and studied, see e.g. Neyman and Sorin [17] in particular Chapters 3, 21, 25, 28.

It has been noticed since Kohlberg and Zamir [6] that games with incomplete information could be analyzed like stochastic games when the information is symmetric: \(c_{n+1} = d_{n+1}\) and contains \((i_n, j_n)\). Since then this approach has been extended, see e.g. Sorin [26] and the analysis in the current article shows that general repeated games with symmetric information are the natural extension of standard stochastic games. However the state variable is no longer \(x_n \in X\) but the (common) conditional probability computed by the players: the law of \(x_n\) in \(\Delta(X)\).
2.2 Borel evaluation and results

We now describe several ways to evaluate each play and the corresponding concepts. We follow the game determinacy literature and define an evaluation function $f$ on infinite plays. Then we study the existence of the value of the normal form game $(\Sigma, T, f)$. We will consider especially four evaluations: the general Borel evaluation, the sup evaluation, the limsup evaluation and the limsup-mean evaluation.

An evaluation is a $H_\infty$-measurable function from the set of plays $H_\infty$ to $[0, 1]$.

**Definition 1.** Given an evaluation $f$, the game $\Gamma$ has a value if
\[
\sup_{\sigma} \inf_{\tau} E_{\sigma,\tau}(f) = \inf_{\tau} \sup_{\sigma} E_{\sigma,\tau}(f).
\]
This real is called the value and denoted by $v(f)$.

Given a repeated game $(\Gamma, g)$, we will study several specific evaluations defined through the stage payoff function $g$.

### 2.2.1 Borel evaluation: sup-evaluation

The first evaluation is the supremum evaluation where a play is evaluated by the largest payoff obtained along it.

**Definition 2.** $\gamma^s$ is the sup evaluation defined by
\[
\forall h \in H_\infty, \gamma^s(h) = \sup_{n \geq 1} g(x_n, i_n, j_n).
\]
In $(\Sigma, T, \gamma^s)$, the max min, the min max, and the value (called the sup-value if it exists) are respectively denoted by $\mathfrak{g}^s$, $\mathfrak{v}^s$ and $v^s$.

The specificity of this evaluation is that for every $n \geq 1$, the maximal stage payoff obtained before $n$ is a lower bound of the evaluation on the current play. We prove that the sup value always exists.

**Theorem 3.** A repeated game $(\Gamma, g)$ with the sup evaluation has a value $v^s$.

In order to prove this result, we use the following result. We call strategic evaluation a function $F$ from $\Sigma \times T$ to $[0, 1]$. It is clear that an evaluation $f$ induces naturally a strategic evaluation by $F(\sigma, \tau) = E_{\sigma,\tau}(f)$.

**Proposition 4.** Let $(F_n)_{n \geq 1}$ be an increasing sequence of strategic evaluations from $\Sigma \times T$ to $[0, 1]$ that converges to some function $F$. Assume that

- $\Sigma$ and $T$ are compact convex sets,
- for every $n \geq 1$, $F_n(\sigma, \cdot)$ is lower semicontinuous and quasiconvex on $T$ for every $\sigma \in \Sigma$,
- for every $n \geq 1$, $F_n(\cdot, \tau)$ is upper semicontinuous and quasiconcave on $\Sigma$ for every $\tau \in T$.

Then the normal form game $(\Sigma, T, F)$ has a value $v$.

A more general version of this proposition can be found in Mertens, Sorin and Zamir [15] (Part A, Exercise 2, section 1.f. p.10).

**Proof of Theorem 3.** Let $n \geq 1$ and define the strategic evaluation $F_n$ by:
\[
F_n(\sigma, \tau) = E_{\sigma,\tau} \left( \sup_{t \leq n} g(x_t, i_t, j_t) \right).
\]
Players remember their own previous actions so by Kuhn’s theorem, there is equivalence between mixed strategies and behaviorial strategies. The sets of mixed strategies are naturally convex. The number of histories of length \( n \) having positive probability is included in a finite set and therefore the set of pure strategies is finite. For every \( n \geq 1 \), the function \( F_n(\sigma, \tau) \) is thus the linear extension of a finite game. In particular \( F_n(\sigma, \cdot) \) is lower semicontinuous and quasiconvex on \( \mathcal{T} \) for every \( \sigma \in \Sigma \) and upper semicontinuous and quasiconcave on \( \Sigma \) for every \( \tau \in \mathcal{T} \).

Finally, the sequence \( (F_n)_{n \in \mathbb{N}} \) is increasing to

\[
F(\sigma, \tau) = \mathbb{E}_{\pi, \sigma, \tau} \left( \sup_t g(x_t, i_t, j_t) \right).
\]

It follows from Proposition 4 that the game \( \Gamma \) with the sup-evaluation has a value.

2.2.2 Borel evaluation: \( \limsup \) evaluation

Several authors have especially focused on the \( \limsup \) evaluation and the \( \limsup \)-mean evaluation.

**Definition 5.** \( \gamma^* \) is the \( \limsup \) evaluation defined by

\[
\forall h \in H^\infty, \; \gamma^*(h) = \limsup_n g(x_n, i_n, j_n).
\]

In \( (\Sigma, \mathcal{T}, \gamma^*) \), the max min, the min max, and the value (called the \( \limsup \) value, if it exists) are respectively denoted by \( \underline{\gamma}^* \), \( \overline{\gamma}^* \) and \( v^* \).

**Definition 6.** \( \gamma_m^* \) is the \( \limsup \)-mean evaluation defined by

\[
\forall h \in H^\infty, \; \gamma_m^*(h) = \limsup_n \frac{1}{n} \sum_{t=1}^n g(x_t, i_t, j_t).
\]

In \( (\Sigma, \mathcal{T}, \gamma_m^*) \), the max min, the min max, and the value (called the \( \limsup \)-mean value, if it exists) are respectively denoted by \( \underline{\gamma}^*_m \), \( \overline{\gamma}^*_m \) and \( v^*_m \).

The \( \limsup \)-mean evaluation is closely related to the \( \limsup \) evaluation. Indeed, the analysis of the \( \limsup \)-mean evaluation of a stochastic game can be reduced to the study of the \( \limsup \) evaluation of an auxiliary stochastic game having as set of states the set of finite histories of the original game.

These evaluations were especially studied by Maitra and Sudderth [8] [9]. They proved the existence of the \( \limsup \) value in a stochastic game with a countable set of states and finite sets of actions when the players observe the state and the actions played. Next they extended in [9] this result to a Borel measurable evaluation.

In general, a repeated game with signals has no value with respect to the \( \limsup \) evaluation as shown in the following three examples. In each case, we also show that the \( \limsup \)-mean value does not exist.

**Example 1.** We consider a recursive game where the players observe neither the state nor the action played by the other player. We say that the players are in the dark.

This example, due to Shmaya, is also described in Rosenberg, Solan and Vieille [22] and can be interpreted as “pick the largest integer”.

The set of states is finite \( X = \{s_1, s_2, s_3, 0^*, 1^*, -1^*, 2^*, -2^*\} \), the action set of player 1 is \( I = \{T, B\} \), the action set of player 2 is \( J = \{L, R\} \), and the transition is given by

\[
\begin{array}{c|cc}
T & L & R \\
\hline
S_1 & s_1 & -2^* \\
S_2 & s_2 \\
\end{array}
\quad
\begin{array}{c|cc}
L & R \\
\hline
1/2(1^*) + 1/2(s_1) & 0^* \\
1/2(-1^*) + 1/2(s_3) \\
\end{array}
\quad
\begin{array}{c|cc}
L & R \\
\hline
s_3 & s_3 \\
2^* & 2^* \\
\end{array}
\]

\( \{\text{guess}\} \)
The computation of the max min with respect to the limsup-mean evaluation is similar to stage $T$.

It follows that player 1 can not guarantee more than $-1/2$ forever, and with probability $1/2$ the next state is $s_3$.

**Claim:** The game which starts in $s_2$ has no limsup value: $v^* = -1/2 < 1/2 = v^*$.

Since the game is recursive, the limsup-mean evaluation and the limsup evaluation coincide, so there is no limsup-mean value either. It also follows that the uniform value, defined formally in Section 4, does not exist.

**Proof:** The situation is symmetric, so we consider what player 1 can guarantee. Given a strategy $\sigma$ of player 1, let $\varepsilon_n$ be the probability that player 1 plays $B$ for the first time at stage $n$ (afterwards the game is essentially over from player 1’s viewpoint), and $\varepsilon^*$ be the probability that player 1 plays $T$ forever.

Player 2 can reply as follows: fix $\varepsilon > 0$, and consider $N$ such that $\sum_{n=N}^{\infty} \varepsilon_n \leq \varepsilon$. Define the strategy $\tau$ which plays $L$ until stage $N - 1$ and $R$ at stage $N$. For any $n > N$, we have:

$$E_{s_2, \sigma, \tau} (g(x_n, i_n, j_n)) \leq \varepsilon^* (-1/2) + \left( \sum_{n=1}^{N-1} \varepsilon_n \right) (-1/2) + \varepsilon (1/2) \leq -1/2 + \varepsilon.$$

It follows that player 1 can not guarantee more than $-1/2$ in the limsup sense. $\square$

**Example 2.** We consider a recursive game where one player is more informed than the other: player 2 observes the state variable and the past actions played whereas player 1 observes neither the state nor the actions played.

This structure of information has been studied for example by Rosenberg, Solan, and Vieille [21], Renault [19], and Gensbittel, Oliu-Barton, and Venel [4]. They proved the existence of the uniform value under the additional assumption that the more informed player controls the evolution of the beliefs of the other player on the state variable.

The set of states is finite $X = \{s_1, s_2, s_3, 0^*, 1/2^*, -1^*, 2^*\}$, the action set of player 1 is $I = \{T, B\}$, the action set of player 2 is $J = \{L, R\}$, and the transition is given by

$$
\begin{array}{ccc}
T & L & R \\
B & s_2 & 1/2(1^*) + 1/2(s_3) \\
     & (-1/2)^* & 0^* \\
\end{array}
\quad
\begin{array}{cc}
L & R \\
  & s_3 & s_3 \\
\end{array}
\quad
\begin{array}{cc}
L & R \\
  & 2^* & 2^* \\
\end{array}
\quad
\begin{array}{c}
s_2 \\
\text{ s_2 } \\
\end{array}
\quad
\begin{array}{c}
s_3 \\
\text{ s_3 } \\
\end{array}
$$

We focus on the game which starts in $s_2$. Both players can guarantee 0 in the sup evaluation by playing respectively $T$ and $L$ forever. Since the game is recursive, the limsup-mean evaluation and the limsup evaluation are equals.

**Claim:** The game which starts in $s_2$ has no limsup value: $v^* = -1/2 < -1/6 = v^*$.

**Proof:** The computation of the max min with respect to the limsup-mean evaluation is similar to the computation of Example 2. The reader can check that player 1 cannot guarantee more than $-1/2$.

We now prove that the min max is equal to $-1/6$. Contrary to Example 2, player 2 observes the state and actions, nevertheless the game is from his strategical point of view finished as soon as $B$ or $R$ is played. Therefore a strategy of player 2 is defined by the probability $\varepsilon_n$ that he plays $R$ for the first time at stage $n$ and the probability $\varepsilon^*$ that he plays $L$ forever.

Fix $\varepsilon > 0$, and consider $N$ such that $\sum_{n=N}^{\infty} \varepsilon_n \leq \varepsilon$. Player 1’s replies can be reduced to the two following strategies: $\sigma_1$ which plays $T$ forever and, $\sigma_2$ which plays $T$ until stage $N - 1$ and $B$ at stage $N$. All the other strategies are yielding a payoff smaller with an $\varepsilon$-error. The strategy $\sigma_1$ yields $0 \varepsilon^* + (1 - \varepsilon^*)(-1/2)$ and the strategy $\sigma_2$ yields $(-1/2)\varepsilon^* + (1 - \varepsilon^*)1/2 - \varepsilon$. 

The previous payoff functions are almost the payoff of the two-by-two game where player 1 chooses $\sigma_1$ or $\sigma_2$ and player 2 chooses either never to play $R$ or to play $R$ at least once.

\[
\begin{pmatrix}
0 & -1/2 \\
-1/2 & 1/2
\end{pmatrix}
\]

The value of this game is $-1/6$, giving the result. \(\square\)

**Example 3.** In the previous examples, the state is not known by both players. Notice that in a game with absorbing payoffs the knowledge of the state is irrelevant. We consider now a stochastic game where both players observe the state. In addition player 2 observes the past actions played whereas player 1 observes only the state.

This game is a variant of the Big Match introduced by Blackwell and Ferguson [2]. In the original version, both player 1 and player 2 were observing the state and past actions.

\[
\begin{pmatrix}
L & R \\
T & 1^* & 0^* \\
B & 0 & 1
\end{pmatrix}
\]

**Claim:** The game with the sup evaluation has a value $v_s = 1$. The game with the limsup evaluation and the game with the limsup-mean evaluation do not have a value: $v^* = v_{\text{sup}}^* = 0 < 1/2 = v_{\text{limsup}}^* = v_{\text{limsup-mean}}^*$.

**Proof:** We first prove the existence of the value with respect to the sup evaluation. Player 1 can guarantee the payoff 1. Let $\varepsilon > 0$, and $\sigma$ be the strategy which plays $T$ with probability $\varepsilon$ and $B$ with probability $1 - \varepsilon$. This strategy yields a sup evaluation greater than $1 - \varepsilon$. Since 1 is the maximum payoff, it is the value: $v_s = 1$.

We now focus on the limsup evaluation and the limsup-mean evaluation. The reader can check that player 1 can not guarantee more than 0 with a proof similar to the one in Example 1 and Example 2 both in the limsup evaluation and the limsup-mean evaluation.

Let us compute what player 2 can guarantee with respect to the limsup evaluation. The computation is similar for the limsup-mean evaluation. First, player 2 can guarantee 1/2 by playing the following mixed strategy: with probability 1/2, play $L$ at every stage and with probability 1/2, play $R$ at every stage.

We now prove that it is the best payoff that player 2 can achieve. Fix a strategy $\tau$ for player 2 and consider the induced law $P$ on the set $H_\infty = \{L, R\}^\infty$ of infinite sequences of $L$ and $R$ induced by $\tau$ when player 1 plays $B$ at every stage. Denote by $\beta_n$ the probability that player 2 plays $L$ at stage $n$. If there exists a stage $N$ such that $\beta_N \geq 1/2$, then playing $B$ until $N - 1$ and $T$ at stage $N$ yields a payoff greater than 1/2 to player 1. If for every $n$, $\beta_n \leq 1/2$, then the payoff at every stage is in expectation smaller than 1/2 and therefore the expected limsup payoff is greater than 1/2. \(\square\)

## 3 Symmetric repeated game with Borel evaluation

Contrary to the sup-evaluation, in general the existence of the value for a given evaluation depends on the signaling structure. In Section 2, we analyzed three games without limsup-mean value. In this section, we prove that if the signaling structure is symmetric as defined next, the value always exists for every evaluation.
3.1 Model and Results

**Definition 7.** A symmetric signaling repeated game form is a repeated game form with signals \( \Gamma = (X, I, J, C, D, \pi, q) \) such that there exists a set \( S \) with \( C = D = I \times J \times S \) satisfying

\[
\forall (x, i, j) \in X \times I \times J, \quad \sum_{s, s'} q(x, i, j)(x', (i, j, s), (i, j, s')) = 1.
\]

and the initial distribution \( \pi \) is also symmetric: \( \pi(x, c, d) > 0 \) implies \( c = d \).

Intuitively, at each stage of a symmetric signaling repeated game form the players observe both actions played and a public signal \( s \). It will be convenient to write such a game form as a tuple \( \Gamma = (X, I, J, C, D, \pi, q) \) and since for such a game:

\[
q(x, i, j)(x', (i', j', s'), (i'', j'', s'')) > 0 \text{ only if } i = i' \text{ and } j = j'' \text{ and } s' = s''
\]

without loss of generality, we can and will write \( q(x, i, j)(x', s) \) as a shorthand for \( q(x, i, j)(x', (i, j, s), (i, j, s)) \). With this notation \( q(x, i, j) \) and the initial distribution \( \pi \) are elements of \( \Delta_I(X \times S) \). The set of observed plays is then \( V_\infty = (S \times I \times J)^\infty \).

**Theorem 8.** Let \( \Gamma \) be a symmetric signaling repeated game form. For every evaluation \( f \), the game \( \Gamma \) has a value.

**Corollary 9.** A symmetric signaling repeated game \( (\Gamma, g) \) has a limsup value and a limsup-mean value.

3.2 Proof of Theorem 8

Let us first give an outline of the proof. Given a symmetric signaling repeated game form \( \Gamma \) and a Borel evaluation \( f \), we construct an auxiliary standard stochastic game \( \tilde{\Gamma} \) (where the players observe the state and the actions) and a Borel evaluation \( \tilde{f} \) on the corresponding set of plays. We use the existence of the value in the game \( \tilde{\Gamma} \) with respect to the evaluation \( \tilde{f} \) to deduce the existence of the value in the original game. The key idea is to define a conditional probability with respect to the \( \sigma \)-algebra of observed plays, compatible with the family of probability distributions generated by the players (Sections 3.2.1-3.2.3). Then we define the function \( \tilde{f} \) and the game \( \tilde{\Gamma} \) (Section 3.2.4) and conclude.
Define \( \alpha \) from \( H \) to \([0, 1]\) where for \( h_n = (x_1, s_1, i_1, j_1, \ldots, x_n, s_n) \):
\[
\alpha(h_n) = \pi(x_1, s_1)\prod_{i=1}^{n-1} q(x_i, i, j_i)(x_{i+1}, s_{i+1})
\]
and similarly, \( \beta \) from \( V \) to \([0, 1]\) where for \( v_n = (s_1, i_1, j_1, \ldots, s_n) \):
\[
\beta(v_n) = \sum_{h_n \in H_n : \Theta(h_n) = v_n} \alpha(h_n).
\]

Let \( \overline{H}_n = \{ h_n \in H_n : \alpha(h_n) > 0 \} \) and \( \overline{V}_n = \Theta(\overline{H}_n) \) and recall that these sets are finite. We introduce now the set of plays that can occur during the game as \( \overline{H}_\infty = \cap_n \overline{H}_n \) and \( \overline{V}_\infty = \Theta(\overline{H}_\infty) = \cap_n \overline{V}_n \). Remark that both are measurable subsets of \( H_\infty \) and \( V_\infty \) respectively.

For every pair of strategies \((\sigma, \tau)\), we denote by \( P_{\sigma,\tau} \) the probability distribution induced over the set of plays \((H_\infty, H_\infty)\) and by \( Q_{\sigma,\tau} \) the probability distribution over the set of observed plays \((V_\infty, V_\infty)\). Thus \( Q_{\sigma,\tau} \) is the image of \( P_{\sigma,\tau} \) under \( \Theta \). Note that \( \text{supp}(P_{\sigma,\tau}) \subset \overline{H}_\infty \). We denote respectively by \( E_{P_{\sigma,\tau}} \) and \( E_{Q_{\sigma,\tau}} \) the corresponding expectations.

It turns out that for technical reasons it is much more convenient to work with the space \( V_\infty \) rather than with \( V_\infty \) (and with \( \overline{H}_\infty \) rather than with \( H_\infty \)). And then, abusing slightly the notation, \( V_\infty \) and \( \overline{V}_n \) will tacitly denote the restrictions to \( V_\infty \) of the corresponding \( \sigma \)-algebras defined on \( V_\infty \). On rare occasions this can lead to a confusion and then we will write for example \( \overline{V}_n \) to denote the \( \sigma \)-algebra \( \{ U \cap V_\infty : U \in \overline{V}_n \} \) the restriction of \( \overline{V}_n \) to \( V_\infty \).

### 3.2.1 Regular conditional probability of finite time events with respect to finite observed histories

For \( m \geq n \geq 1 \) we define \( \Phi_{n,m} \) from \( H_\infty \times V_\infty \) to \([0, 1]\) by:
\[
\Phi_{n,m}(h, v) = \begin{cases} 
\sum \{ h', h'_m = h|m, \Theta(h'|m) = v|m \} \alpha(h'_m) \beta(v|m) & \text{if } \Theta(h|n) = v|n \\
0 & \text{otherwise.}
\end{cases}
\]

This corresponds to the joint probability of the players on the realization of the history \( h \) up to stage \( n \), given the observed history \( v \) up to stage \( m \).

Since \( \Phi_{n,m}(h, v) \) depends only on \( h|n \) and \( v|m \) we can see \( \Phi_{n,m} \) as a function defined on \( H_n \times V_m \) and note that its support is included in \( \overline{H}_n \times \overline{V}_m \). On the other hand, since each set \( U \in H_n \) is a finite union of cylinders \( h^+_n \) for \( h_n \in H_n \) such that \( h^+_n \subset U \), \( \Phi_{n,m} \) can be seen as a mapping from \( H_n \times V_\infty \) into \([0, 1]\), where \( \Phi_{n,m}(U, v) = \sum_{h_n, h'_n \subseteq U} \Phi_{n,m}(h_n, v) \). Bearing this last observation in mind we have:

**Lemma 10.** For every \( m \geq n \geq 1 \), \( \Phi_{n,m} \) is a probability kernel from \((\overline{V}_\infty, V_m)\) to \((H_\infty, H_n)\).

**Proof.** Since \( \sum_{h_n \in H_n} \Phi_{n,m}(h_n, v) = 1 \) for \( v \in \overline{V}_\infty \), \( \Phi_{n,m}(\cdot, v) \) defines a probability on \( H_n \). Moreover, for any \( U \in H_n \), \( \Phi_{n,m}(U, v) \) is a function of the \( m \) first components of \( v \) hence is \( V_m \)-measurable. \( \square \)

**Lemma 11.** Let \( m \geq n \geq 1 \) and \((\sigma, \tau)\) be a pair of strategies. Then, for every \( v_m \in V_m \) such that \( Q_{\sigma,\tau}(v_m) = P_{\sigma,\tau}(v_m) > 0 \), and every \( h_n \in H_n \):
\[
P_{\sigma,\tau}(h_n^+|v_m^+) = \Phi_{n,m}(h_n, v_m).
\]

**Proof.** Let \( v_m = (s_1, i_1, j_1, \ldots, s_m) \) and \( h_n \in H_n \).
\[
P_{\sigma,\tau}(h_n^+|v_m^+) = \frac{P_{\sigma,\tau}(h_n^+ \cap v_m^+)}{P_{\sigma,\tau}(v_m^+)} = \begin{cases} 
\sum \{ h', h'_m = h|m, \Theta(h'|m) = v_m \} \alpha(h'_m)W(i_1, j_1, \ldots, j_{m-1}) & \text{if } \Theta(h|n) = v_m|n \\
0 & \text{otherwise.}
\end{cases}
\]

9
where $W(i_1, j_1, \ldots, j_{m-1}) = \Pi_{t \leq m-1} \sigma(v_{m|t})(i_t) \tau(v_{m|t})(j_t)$. After simplification, we recognize on the right the definition of $\Phi_{n,m}(v_m, h_n)$.

We deduce the following lemma:

**Lemma 12.** For every pair of strategies $(\sigma, \tau)$, each $W \in \overline{V}_m$ and $U \in \mathcal{H}_n$ we have:

\[
\mathbb{P}_{\sigma,\tau}(U \cap \Theta^{-1}(W)) = \int_W \Phi_{n,m}(U, v) Q_{\sigma,\tau}(dv). \tag{1} \]  

**Proof.** Clearly it suffices to prove (1) for cylinders $U = h_n^+$ and $W = v_m^+$ with $\beta(v_m) > 0$.

We have
\[
\int_{v_m^+} \Phi_{n,m}(h_n, v) Q_{\sigma,\tau}(dv) = \Phi_{n,m}(h_n, v_m) Q_{\sigma,\tau}(v_m^+) = \mathbb{P}_{\sigma,\tau}(h_n^+ | v_m^+) Q_{\sigma,\tau}(v_m^+) = \mathbb{P}_{\sigma,\tau}(h_n^+ \cap v_m^+). \tag{2} \]

Note that (1) can be equivalently written as: for every pair of strategies $(\sigma, \tau)$, each $W^* \in \overline{V}_m$ and $U \in \mathcal{H}_n$
\[
\mathbb{P}_{\sigma,\tau}(U \cap W^*) = \int_{W^*} \Phi_{n,m}(U, \Theta(h)) \mathbb{P}_{\sigma,\tau}(dh). \tag{3} \]

### 3.2.2 Regular conditional probability of finite time events with respect to infinite observed histories

In this paragraph, we prove that instead of defining one application $\Phi_{n,m}$ for every pair $(m, n)$ such that $m \geq n \geq 1$, one can define a unique probability kernel $\Phi_n$ from $(\Omega_n, \mathcal{V}_\infty)$ to $(H_\infty, \mathcal{H}_n)$, with $Q_{\sigma,\tau}(\Omega_n) = 1$, for all $(\sigma, \tau)$, such that the extension of Lemma 12 holds.

For $h \in H_\infty$, let
\[
\Omega_h = \{ v \in \overline{V}_\infty | \Phi_{n,m}(h, v) \text{ converges as } m \uparrow \infty \}. \]

The domain $\Omega_h$ is measurable (see Kallenberg [5] p.6 for example). Recall that $\Omega_h$ depends only on $h|_n$ and write also $\Omega_{h|n}$ for $\Omega_h$. Let then
\[
\Omega_n = \bigcap_{h \in H_n} \Omega_{h|n}. \]

We define $\Phi_n : H_\infty \times \overline{V}_\infty \rightarrow [0, 1]$ by $\Phi_n = \lim_{m \rightarrow \infty} \Phi_{n,m}$ on $H_\infty \times \Omega_n$ and 0 otherwise. As a limit of a sequence of measurable mappings $\Phi_n$ is measurable (see Kallenberg [5] p.6 for example).

**Lemma 13.** (i) For each pair of strategies $(\sigma, \tau)$, $Q_{\sigma,\tau}(\Omega_n) = 1$.

(ii) For each $v \in \Omega_n$, $\sum_{h \in H_n} \Phi_n(h_n, v) = 1$.

(iii) For each $U \in \mathcal{H}_n$ the mapping $v \mapsto \Phi_n(U, v)$ is a measurable mapping from $(\overline{V}_\infty, \mathcal{V}_\infty)$ to $\mathbb{R}$.

(iv) For each pair of strategies $(\sigma, \tau)$, for each $U \in \mathcal{H}_n$ and each $W \in \mathcal{V}_\infty$
\[
\mathbb{P}_{\sigma,\tau}(U \cap \Theta^{-1}(W)) = \int_W \Phi_n(U, v) Q_{\sigma,\tau}(dv). \tag{3} \]
Proof. (i) For $h_n \in H_n$ and each pair of strategies $\sigma, \tau$ we define on $H_\infty$ a sequence of random variables $Z_{h_n,m}$, $m \geq n$, 

$$Z_{h_n,m} = \mathbb{P}_{\sigma,\tau}[h_n^+ | Y_m^\sigma].$$

As a conditional expectation of a bounded random variable with respect to an increasing sequence of $\sigma$-algebras, $Z_{h_n,m}$ is a martingale (with respect to $\mathbb{P}_{\sigma,\tau}$), hence converges $\mathbb{P}_{\sigma,\tau}$-almost surely and in $L^1$ to the random variable $Z_{h_n} = \mathbb{P}_{\sigma,\tau}[h_n^+ | Y_\infty^\sigma]$.

For $m \geq n$, we define the mappings $\psi_{n,m}[h_n] : \mathcal{F}_\infty \to [0,1]$, 

$$\psi_{n,m}[h_n](h) = \Phi_{n,m}(h_n, \Theta(h)),$$

Let us show that for each $h_n \in H_n$, $\psi_{n,m}[h_n]$ is a version of the conditional expectation $\mathbb{E}_{\sigma,\tau} \mathbb{P}_{\sigma,\tau}[h_n^+ | V_m^\sigma] = \mathbb{P}_{\sigma,\tau}[h_n^+ | V_m^\sigma]$. First note that $\psi_{n,m}[h_n]$ is $(H_\infty, V_m^\sigma)$ measurable. Lemma 11 implies that, for $h \in \text{supp}(\mathbb{P}_{\sigma,\tau}) \subset \mathcal{F}_\infty$, $\psi_{n,m}[h_n](h) = \Phi_{n,m}(h_n, \Theta(h)) = \mathbb{P}_{\sigma,\tau}(h_n^+ | v_m^\sigma) = \mathbb{P}_{\sigma,\tau}(h_n^+ | V_m^\sigma)(h)$, where $v = \Theta(h)$. Hence the claim.

Since $\psi_{n,m}[h_n]$ is a version of $\mathbb{P}_{\sigma,\tau}(h_n^+ | V_m^\sigma)$, its limit $\psi_n[h_n]$ exists and is a version of $\mathbb{P}_{\sigma,\tau}(h_n^+ | V_\infty^\sigma)$, $\mathbb{P}_{\sigma,\tau}$-almost surely. In particular

(C1) the set $\Theta^{-1}(\Omega_n) = \{h \in H_\infty \mid \lim_m \psi_{n,m}(h_n)(h) \text{ exists}\}$ is $V_\infty^\sigma$ measurable and has $\mathbb{P}_{\sigma,\tau}$-measure 1,

(C2) for each $W^* \in V_\infty^\sigma$, $\int_{W^*} \psi_n[h_n](h) \mathbb{P}_{\sigma,\tau}(dh) = \int_{W^*} \mathbb{E}[h_n^+ | V_\infty^\sigma] \mathbb{P}_{\sigma,\tau} = \mathbb{P}_{\sigma,\tau}(W^* \cap h_n^+)$. 

Note that (C1) implies that $Q_{\sigma,\tau}(\Omega_n) = 1$.

(ii) If $v \in \Omega_n$ then, for all $h_n \in H_n$, $\psi_{n,m}(h_n, v)$ converges to $\Phi_n(h_n, v)$. But, by Lemma 10, $\sum_{h_n \in H_n} \Phi_n(h_n, v) = 1$. The sum being with finitely many non-zero terms one has $\sum_{h_n \in H_n} \Phi_n(h_n, v) = 1$.

(iii) was proved before the Lemma.

(iv) Since $\int_W \Phi_n(h_n, v) Q_{\sigma,\tau}(dv) = \int_{\Theta^{-1}(W)} \psi_n[h_n](h) \mathbb{P}_{\sigma,\tau}(dh)$ for $W \in V_\infty$, using (C2) we get

$$\mathbb{P}_{\sigma,\tau}(h_n^+ \cap \Theta^{-1}(W)) = \int_W \Phi_n(h_n, v) Q_{\sigma,\tau}(dv)$$

for $U \in V_\infty$. \hfill \Box

3.2.3 Regular conditional probability of infinite time events with respect to infinite observed histories

In this section, using Kolmogorov extension theorem we construct from the sequence $\Phi_n$ of probability kernels from $(\Omega_n, V_n)$ to $(H_\infty, H_n)$, one probability kernel $\Phi$ from $(\Omega_\infty, V_\infty)$ to $(H_\infty, H_n)$, with $Q_{\sigma,\tau}(\Omega_\infty) = 1$, for all $(\sigma, \tau)$.

Lemma 14. There exists a measurable subset $\Omega_\infty$ of $V_\infty$ such that, for all strategies $\sigma, \tau$, \hfill \{sec:trzy\}

• $Q_{\sigma,\tau}(\Omega_\infty) = 1$ and

• there exists a probability kernel $\Phi$ from $(\Omega_\infty, V_\infty)$ to $(H_\infty, H_n)$ such that for each $W \in V_\infty$ and $U \in H_\infty$

$$\mathbb{P}_{\sigma,\tau}(U \cap \Theta^{-1}(W)) = \int_W \Phi(U, v) Q_{\sigma,\tau}(dv).$$ \hfill \{eq:final\}
Before proceeding to the proof some remarks are in order.

A probability kernel having the property given above is called a regular conditional probability.

For given strategies $\sigma$ and $\tau$ the existence of a transition kernel $\kappa_{\sigma,\tau}$ from $(V_\infty, V_\infty)$ to $(H_\infty, H_\infty)$ such that for each $U \in V_\infty$ and $A \in H_\infty$

$$\mathbb{P}_{\sigma,\tau}(A \cap \Theta^{-1}(U)) = \int_U \kappa_{\sigma,\tau}(A, v) \, Q_{\sigma,\tau}(dv)$$

is well known provided that $V_\infty$ is a Polish space and $V_\infty$ is the Borel $\sigma$-algebra. In the current framework it is easy to introduce an appropriate metric on $V_\infty$ such that this condition is satisfied thus the existence of $\kappa_{\sigma,\tau}$ is immediately assured.

The difficulty in our case comes from the fact that we look for a regular conditional probability which is common for all probabilities $\mathbb{P}_{\sigma,\tau}$, where $(\sigma, \tau)$ range over all strategies of both players.

**Proof.** We follow the notations of the proof of Lemma 13 and define $\Omega_\infty = \cap_{n \geq 1} \Omega_n$. Let $(\sigma, \tau)$ be a couple of strategies. For every $n \geq 1$, $Q_{\sigma,\tau}(\Omega_n) = 1$, hence $Q_{\sigma,\tau}(\Omega_\infty) = 1$. By Lemma 13(ii), given $v \in \Omega_\infty$, the sequence $\{\Phi_n(\cdot, v)\}_{n \geq 1}$ of probabilities on $\{(H_\infty, H_\infty)\}_{n \geq 1}$ is well defined. Let us show that this sequence satisfies the condition of Kolmogorov’s extension theorem.

In fact $\Phi_{n,m}(\cdot, v)$ is defined on the power set of $H_n$ by

$$\forall \ A \subset H_n \ , \ \Phi_{n,m}(A, v) = \sum_{h_n \in A} \Phi_{n,m}(h_n, v).$$

Thus for every $h_n \in H_n$, we have

$$\Phi_{n,m}(h_n, v) = \frac{\mathbb{P}_{\sigma,\tau}(v^+_m \cap h_n^+)}{\mathbb{P}_{\sigma,\tau}(v^+_m)} = \frac{\mathbb{P}_{\sigma,\tau}(v^+_m \cap (h_n \times I \times J \times X \times S^+) + \mathbb{P}_{\sigma,\tau}(v^+_m)} = \Phi_{n+1,m}(h_n \times (I \times J \times X \times S), v).$$

Taking the limit, we obtain the same equality for $\Phi_n$ and $\Phi_{n+1}$ hence the compatibility condition. By the Kolmogorov extension theorem for each $v \in \Omega$ there exists a measure $\Phi(\cdot, v)$ on $(H_\infty, H_\infty)$ such that

$$\Phi(h_n^+, v) = \Phi_n(h_n^+, v)$$

for each $n$ and each $h_n \in H_n$.

Let us prove that, for each $U \in \mathcal{H}_\infty$, the mapping $v \mapsto \Phi(U, v)$ is $\mathcal{V}_\infty$-measurable on $\Omega_\infty$.

Let $\mathcal{C}$ be the class of sets $A \in \mathcal{H}_\infty$ such that $\Phi(A, \cdot)$ has this property. By Lemma 13, $\mathcal{C}$ contains the $\pi$-system consisting of cylinders generating $\mathcal{H}_\infty$. To show that $\mathcal{H}_\infty \subseteq \mathcal{C}$ it suffices to show that $\mathcal{C}$ is a $\lambda$-system. Let $A_1$ be an increasing sequence of sets belonging to $\mathcal{C}$. Since, for each $v \in \mathcal{V}_\infty$, $\Phi(\cdot, v)$ is a measure, we have $\Phi(\cup_n A_n, v) = \sup_n \Phi(A_n, v)$. However, $v \mapsto \sup_n \Phi(A_n, v)$ is measurable as a supremum of measurable mappings $v \mapsto \Phi(A_n, v)$. Let $A \supset B$ be two sets belonging to $\mathcal{C}$. Then $\Phi(A \setminus B, v) + \Phi(B, v) = \Phi(A, v)$ by additivity of measure and $v \mapsto \Phi(A \setminus B, v) = \Phi(A, v) - \Phi(B, v)$ is measurable as a difference of measurable mappings.

To prove (4), take a measurable subset $W$ of $\overline{\mathcal{V}}_\infty$ and consider the set function

$$\mathcal{H}_\infty \ni U \mapsto \int_W \Phi(U, dv)Q_{\sigma,\tau}(dv).$$

Since $\Phi(\cdot, v)$ is nonnegative this set function is a measure on $(H_\infty, \mathcal{H}_\infty)$. However by Lemma (13) this mapping is equal to $U \mapsto \mathbb{P}_{\sigma,\tau}(U \cap \Theta^{-1}(W))$ for $U$ belonging to the $\pi$-system of cylinders.
generating $\mathcal{H}_\infty$. But two measures equal on a generating $\pi$-system are equal, which terminates the proof of (4).

A standard property of probability kernels and the fact that $\Omega_\infty$ has measure 1 imply:

**Corollary 15.** Let $f : \mathcal{H}_\infty \to [0, 1]$ be $\mathcal{H}_\infty$-measurable mapping. Then the mapping $\hat{f} : V_\infty \to [0, 1]$ defined by:

$$\hat{f}(v) = \begin{cases} \int_{\mathcal{H}_\infty} f(h) \Phi(dh, v) & \text{if } v \in \Omega_\infty, \\ 0 & \text{otherwise} \end{cases}$$

is $\mathcal{V}_\infty$-measurable and

$$E_{P_{\sigma,\tau}}[f] = E_{Q_{\sigma,\tau}}[\hat{f}], \quad \forall \sigma, \tau.$$

### 3.2.4 Conclusion

Given a symmetric signaling repeated game $\Gamma$ we define a stochastic game $\hat{\Gamma}$. The sets of actions $I$ and $J$ are the same as in $\Gamma$. The set of states is $V = \cup_{n \geq 1} V_n$ and the transition $\hat{q}$ from $V \times I \times J$ to $\Delta(V)$ is given by

$$\forall v_n \in V_n, \forall i \in I, \forall j \in J, \quad \hat{q}(v_n, i, j) = \sum_{s \in S} \psi(v_n, i, j, s) \delta_{v_n, i, j, s},$$

where $\psi(v_n, i, j, s) = \frac{\beta(v_n, i, j, s)}{\beta(v_n)}$.

Note that if $v_n \in V_n$ then the support of $\hat{q}(v_n, i, j)$ is included in $V_{n+1}$, in particular is finite. Moreover, if $\hat{q}(v_n, i, j)(v_{n+1}) > 0$ then $v_{n+1}|n = v_n$.

The initial distribution of $\hat{\Gamma}$ is the marginal distribution $\pi^S$ of $\pi$ on $S$, if $s \in S = V_1$, then $\pi^S(s) = \sum_{x \in X} \pi(x, s)$ and $\pi^S(v) = 0$ for $v \in V \setminus V_1$.

Let us note that the original game $\Gamma$ and the auxiliary game $\hat{\Gamma}$ have the same sets of strategies.

Indeed a behavioral strategy in $\Gamma$ is a mapping from $V$ to probability distributions over actions. Thus each behavioral strategy in $\Gamma$ is a stationary strategy in $\hat{\Gamma}$. On the other hand however, each state of $\hat{\Gamma}$ "contains" all previously visited states and all played actions thus, for all useful purposes, in $\hat{\Gamma}$ behavioral strategies and stationary strategies coincide.

Now suppose that $(v_1, i_1, j_1, v_2, i_2, j_2, \cdots)$ is a play in $\hat{\Gamma}$. Then $v_{n+1}|n = v_n$ for all $n$ and there exists $v \in V_\infty$ such that $v_n|n = v_n$ for all $n$. Thus defining a payoff on infinite histories in $\hat{\Gamma}$ amounts to defining a payoff on $V_\infty$. Given a Borel function $f$ on $H_\infty$ consider the function $\hat{f}$ defined in Corollary 15. It satisfies

$$E_{P_{\sigma,\tau}}[f] = E_{Q_{\sigma,\tau}}[\hat{f}], \quad \forall \sigma, \tau.$$  \hfill (5)  \hfill (eq_final)

i.e. the result of playing in $\Gamma$ with strategies $(\sigma, \tau)$ and payoff $f$ is the same as playing in $\hat{\Gamma}$ with the same strategies and payoff $\hat{f}$.

By Martin [14] or Maitra and Sudderth [12], the stochastic game $\hat{\Gamma}$ with payoff $\hat{f}$ has value implying that $\Gamma$ with payoff $f$ has value.

**Remark 1.** The same proof applies for an $N$-person game form with symmetric signaling: the players know the previous moves and a common public signal on the state and have Borel payoff functions $f_m, m = 1, \cdots, N$.  

13
4 Uniform value in recursive games with non-negative payoffs

In Section 2 and Section 3, we focused on Borel evaluations. In this last Section, we focus on the family of mean average of the $n$ first stage payoffs and the corresponding uniform value.

**Definition 16.** For each $n \geq 1$, the mean expected payoff induced by $(\sigma, \tau)$ during the first $n$ stages is:

$$\gamma_n(\sigma, \tau) = E_{\sigma, \tau} \left( \frac{1}{n} \sum_{t=1}^{n} g(x_t, i_t, j_t) \right).$$

**Definition 17.** Let $v$ be a real number. A strategy $\sigma^*$ of player 1 guarantees $v$ in the uniform sense in $(\Gamma, g)$ if for all $\eta > 0$ there exists $n_0 \geq 1$ such that

$$\forall n \geq n_0, \forall \tau \in \mathcal{T}, \gamma_n(\sigma^*, \tau) \geq v - \eta.$$

Player 1 can guarantee $v$ in the uniform sense in $(\Gamma, g)$ if for all $\varepsilon > 0$ there exists a strategy $\sigma^* \in \Sigma$ which guarantees $v - \varepsilon$ in the uniform sense.

**Remark 2.** For $n \geq 1$, the $n$-stage game $(\Gamma_n, g)$ is the zero-sum game with normal form $(\Sigma, \mathcal{T}, \gamma_n)$ and value $v_n$. It is interesting to note that in the special case of symmetric signaling repeated games with a finite set of states and finite set of signals, a uniform value may not exist, since even the sequence of values $v_n$ may not converge (Ziliotto [27]), but there exists a value for any Borel evaluation by Theorem 8.

We focus now on the specific case of recursive games with non-negative payoff defined as follows.

**Definition 19.** A state is absorbing if the probability to stay in this state is 1 for all actions and the payoff is also independent of the actions played. A repeated game is recursive if the payoff is equal to 0 outside the absorbing states. If all absorbing payoffs are non-negative, the game is recursive and non-negative.

Solan and Vieille [24] have shown the existence of a uniform value in non-negative recursive games where the players observe the state and past actions played. We show that the result is true without assumption on the signals to the players.

In a recursive game, the limsup-mean evaluation and the limsup evaluation coincide. If the recursive game has non-negative payoffs, the sup-evaluation, the limsup evaluation and the
Using the monotone convergence theorem, we also have thus player 1 guarantees $Hence the strategy $\sigma$ in $\Gamma$ converges and the lim sup can be replaced by a limit.

Denote $v = \sup_n v_n$ and let us show that $v$ is the uniform value.

Fix $\varepsilon > 0$, consider $N$ such that $v_N \geq v - \varepsilon$ and $\sigma^*$ a strategy of player 1 which is optimal in $\Gamma_N$. We have for each $\tau$ and, for every $n \geq N$,

$$\gamma_n(\sigma^*, \tau) \geq \gamma_N(\sigma^*, \tau) \geq v_N \geq v - \varepsilon.$$ 

Hence the strategy $\sigma^*$ guarantees $v - \varepsilon$ in the uniform sense. This is true for every positive $\varepsilon$, thus player 1 guarantees $v$ in the uniform sense.

Using the monotone convergence theorem, we also have

$$\gamma^*(\sigma^*, \tau) = E_{\sigma^*, \tau} \left( \lim_{n} \frac{1}{n} \sum_{t=1}^{n} g(x_t, i_t, j_t) \right) = \lim_{n} E_{\sigma^*, \tau} \left( \frac{1}{n} \sum_{t=1}^{n} g(x_t, i_t, j_t) \right) \geq v - \varepsilon.$$ 

We now show that player 2 can also guarantee $v$ in the uniform sense. Consider for every $n$, the set:

$$K_n = \{ \tau, \forall \sigma, \gamma_n(\sigma, \tau) \leq v \}.$$ 

$K_n$ is non empty because it contains an optimal strategy for player 2 in $\Gamma_n$ (since $v_n \leq v$).

The set of strategies of player 2 is compact, hence by continuity of the $n$-stage payoff $\gamma_n$, $K_n$ is itself compact. $\gamma_n \leq \gamma_{n+1}$ implies $K_{n+1} \subseteq K_n$ hence $\cap_n K_n \neq \emptyset$: there exists $\tau^*$ such that for every strategy of player 1, $\sigma$ and for every positive integer $n$, $\gamma_n(\sigma, \tau) \leq v$. It follows that both players can guarantee $v$, thus $v$ is the uniform value.

By the monotone convergence theorem, we also have

$$\gamma^*(\sigma, \tau^*) = E_{\sigma, \tau^*} \left( \lim_{n} \frac{1}{n} \sum_{t=1}^{n} g(x_t, i_t, j_t) \right) = \lim_{n} E_{\sigma, \tau^*} \left( \frac{1}{n} \sum_{t=1}^{n} g(x_t, i_t, j_t) \right) \leq v.$$ 

Hence $v$ is the sup and limsup value.

**Remark 3.** The fact that the sequence of $n$-stage values $(v_n)_{n \geq 1}$ is non decreasing is not enough to ensure the existence of the uniform value. For example, consider the Big Match [2] with no signals: $v_n = 1/2$ for each $n$ but there is no uniform value.

**Remark 4.** The theorem states the existence of a $0$-optimal strategy for player 2 but player 1 may only have $\varepsilon$-optimal strategies. For example, in the following MDP, there are two absorbing states, two non-absorbing states with payoff 0 and two actions **Top** and **Bottom**:

$$
\begin{pmatrix}
1/2(s_1) + 1/2(s_2) & s_2 \\
0 & s_1
\end{pmatrix}
\begin{pmatrix}
s_2 \\
1^*
\end{pmatrix}
$$
The starting state is $s_1$ and player 1 observes nothing. A good strategy is to play Top for a long time and then Bottom. While playing Bottom, the process absorbs and with a strictly positive probability the absorption occurs in state $s_1$ with absorbing payoff 0. So player 1 has no strategy which guarantees the uniform value of 1.
