ABSTRACT: This paper presents a reliability-based approach for the analysis and design of a shallow strip footing subjected to an eccentric load. Only the punching failure mode of the ultimate limit state is considered in this paper. The deterministic model used is based on two rotational double-spiral failure mechanisms in limit analysis. The random variables used are the soil shear strength parameters. The hypothesis of uncorrelated shear strength parameters was found conservative in comparison to the one of negatively correlated variables. The coefficient of variation of only the angle of internal friction has a significant effect on the failure probability. For design, an iterative procedure is performed to determine the breadth of the footing for a target failure probability.

INTRODUCTION

Several authors have investigated the reliability-based analysis of foundations. Some of them (e.g. Fenton and Griffiths 2003) have modelled the uncertain parameters as random processes and have examined the effect of the spatial variability of these parameters on the bearing capacity of footings. Others have modelled the uncertainties of the different parameters as random variables and have conducted a reliability-based analysis by using empirical formulas for the bearing capacity factors (e.g. Low and Phoon 2002). These approaches have the advantage of being simple; however, they present some shortcomings because they are based on approximate formulae. Also, to the authors' knowledge, there are no extensive investigations on the reliability analysis or design of footings subjected to an eccentric load. In this paper, a reliability-based analysis and design of a strip footing resting on a \((c-\phi)\) soil and subjected to an eccentric load is presented. Only the punching mode of the ultimate limit state is analysed. A limit analysis deterministic model is used. The soil shear strength...
parameters are modelled as random variables which implies an assumption of an infinite
correlation length. This may lead to unconservative estimates of the reliability index or
failure probability (cf. Fenton and Griffiths 2003). A more rigorous approach dealing
with the uncertainties of the soil parameters as random fields should thus be investigated
in the future. After an overview of the reliability concepts, the probabilistic model and
the corresponding numerical results are presented and discussed.

**OVERVIEW OF RELIABILITY CONCEPTS**

Two different measures are commonly used in literature to describe the reliability of a
structure: The *reliability index* and the *failure probability*. The reliability index is a
measure of the safety that takes into account the inherent uncertainties of the input
variables. The widely used reliability index is the one defined by Hasofer and Lind. Its
matrix formulation is given by:

\[ \beta_{HL} = \min_{x \in F} \sqrt{(x - \mu)^T C^{-1} (x - \mu)} \]  

in which \( x \) = vector representing the \( n \) random variables, \( \mu \) = vector of their mean values,
\( C \) = covariance matrix and \( F \) = failure region. The minimisation of (1) is performed over
the failure domain \( F \) corresponding to the region \( G(x) \leq 0 \) where the hyper-surface
\( G(x) = 0 \), referred to as the limit state surface, separates the \( n \)-dimensional domain of
random variables in two regions: a failure region represented by \( G(x) \leq 0 \) and a safe
region given by \( G(x) > 0 \). The classical approach for computing \( \beta_{HL} \) using (1) is based
on the transformation of the limit state surface into the space of standard normal
uncorrelated variates. The shortest distance from the transformed failure surface to the
origin of the reduced variates is the reliability index \( \beta_{HL} \). An intuitive interpretation of
the Hasofer-Lind reliability index was suggested in Low and Tang (1997) where the
concept of an expanding ellipsoid led to a simple method of computing \( \beta_{HL} \) in the
original space of the random variables. These authors stated that the minimization of the
reliability index is equivalent to find the smallest dispersion ellipsoid that is tangent to
the limit state surface and whose centre is at the equivalent normal mean point of the
random variables. This ellipsoid is called 'critical dispersion ellipsoid' and the ellipsoid
 correponding to \( \beta_{HL} = 1 \) in eq (1) without the min is named 'unit dispersion ellipsoid'.
The ratio between the critical dispersion ellipsoid and the unit dispersion one is the
Hasofer-Lind reliability index. The computation of the equivalent normal mean and
standard deviation for each trial design point are automatically found during the
constrained optimization search. The method of computation of the reliability index
suggested by Low and Tang (1997) is used in this paper.
The aim of this paper is to perform a reliability analysis of a strip footing resting on a c-\(\varphi\) soil and subjected to an eccentric load. The deterministic model is based on the upper-bound method of limit analysis using two kinematically admissible failure mechanisms. The first mechanism is referred to here as \(M1\) (Figure 1). This mechanism is composed of a central shear zone \(BCD\) sandwiched between a rigid block \(ABC\) and a triangular shear zone \(BDE\).

The first block \(ABC\) adjacent to the footing is bounded by a log-spiral slip surface \(AC\). This block undergoes a rigid body rotation about the as yet undefined center of rotation \(O\). Thus, the velocity along any radial line (say \(BC\)) varies linearly. The block \(BCD\) is bounded by a log-spiral slip surface which is tangent to lines \(AC\) and \(DE\) respectively at \(C\) and \(D\). It is subject to radial and orthoradial shear. Finally, the block \(BDE\) undergoes a simple shear along lines parallel to line \(DE\). This mechanism is described by 3 angular parameters \(\alpha\), \(\beta\) and \(\psi\). Note that the foundation is assumed to be adherent to the soil mass along the whole soil-foundation interface, i.e. \(AB\). The second failure mechanism is referred to here as \(M2\) mechanism. \(M2\) resembles \(M1\) mechanism. The only difference is that \(M2\) mechanism allows some separation along the soil-foundation interface. Thus, the footing is assumed to be adherent to the soil mass only along \(\lambda \cdot B\) where \(0 < \lambda < 1\). In the \(M2\) mechanism, the slip surface \(AC\) is assumed to be tangent to the foundation at \(A\). Notice that point \(A\) moves horizontally to the right as the eccentricity increases. This mechanism is described by 4 parameters \(\alpha\), \(\beta\), \(\psi\) and \(\lambda\). It is particularly interesting for large load eccentricities. As expected, \(M1\) mechanism provides the lowest solutions of the ultimate bearing capacity for small eccentricities; however for high eccentricities, \(M2\) gives smaller (i.e. better) results because of the
separation permitted on the soil-foundation interface. The minimal values between both $M1$ and $M2$ mechanisms are adopted in the present analysis.

Due to uncertainties in soil shear strength parameters, the cohesion $c$ and the angle of internal friction $\varphi$ are considered as random variables. The performance function of the punching mode is defined with respect to the bearing failure of the soil. It is given by:

$$G = P_u / P - 1 = F_p - 1,$$

where $P_u$ and $P$ are the ultimate foundation load and the service applied load respectively and $F_p$ is the punching safety factor.

In this paper, one literally sets up a tilted ellipsoid in a spreadsheet and minimizes the dispersion ellipsoid subject to the constraint that it be tangent to the limit state surface. The minimization of equation 1 is performed not only with respect to the random variables, but also with respect to the geometrical parameters of the failure mechanism. The obtained surface corresponding to the minimum reliability index is referred to here as the critical probabilistic surface. The reliability index obtained using this surface is smaller (i.e. more critical) than the one calculated by using the critical deterministic surface.

**NUMERICAL RESULTS**

The numerical results presented in this paper consider the case of a strip foundation with breadth $B = 2$ m. The soil has a unit weight of 18 kN/m$^3$. The illustrative values used for the statistical moments of the shear strength parameters and their coefficient of correlation $\rho_{c,\varphi}$ are given as follows: $\mu_c = 20$ kPa, $\mu_{\varphi} = 30^\circ$, $COV_c = 20\%$, $COV_{\varphi} = 10\%$ and $\rho_{c,\varphi} = -0.5$. Notice that $c$ and $\varphi$ are unlikely to be positively correlated. This may be explained by the linear Mohr-Coulomb failure criterion: when $c$ increases, $\varphi$ decreases. Experimental research is needed in order to confirm this commonly used assumption. For the probability distribution of the random variables, two cases are studied. In the first case referred to as normal variables, $c$ and $\varphi$ are considered as normal variables. In the second case referred to as non-normal variables, $c$ is assumed to be log-normally distributed while $\varphi$ is assumed to be bounded and a beta distribution is used (e.g. Fenton and Griffiths, 2003). The parameters of the beta distribution are determined from the mean value and standard deviation of $\varphi$. For both cases, correlated and uncorrelated shear strength parameters are considered.

For the mean values of the soil shear strength parameters, the critical eccentricity is equal to 0.11B. This corresponds to the value of the eccentricity beyond which separation may occur at the soil-footing interface. In the following sections, (i) a smaller eccentricity of 0.05B for which $M1$ is the most critical mechanism in a reliability analysis and, (ii) a greater eccentricity of 0.3B for which $M2$ mechanism becomes the most critical, are employed. The reason why $M1$ is suitable for $e/B=0.05$ and $M2$ for $e/B=0.3$ may be explained as follows: the failure mechanism used ($M1$ or $M2$) for the
determination of the ultimate load \( P_u \) in the punching performance function is only dependent on the eccentricity ratio.

### Reliability index, design point and failure probability

Tables 1-2 present the reliability results \( i.e. \) Hasofer-Lind reliability index, FORM failure probability, the design point \( (c^*, \varphi^*) \) and the resistance factors \( F_c = \mu_c / c^* \), \( F_\varphi = \tan(\mu_\varphi / \tan \varphi^* ) \) for different values of the applied load \( P \) and for two values of the eccentricity ratio \( (e/B=0.05 \; ; \; 0.3) \). The case of non-normal and correlated variables is considered in these tables. Columns 2 of these tables give the values of the deterministic punching safety factor \( F_p \) computed based on the mean values of the random variables.

For both tables, the reliability index decreases with the increase of \( P \) \( i.e. \) with the decrease of the deterministic safety factor \( F_p \) until it vanishes when the ultimate state of failure is reached. This ultimate state is the one for which the design point is equal to the equivalent normal mean point of the random variables. The corresponding failure probability is equal to 50%. The values of \( c^* \) and \( \varphi^* \) at the design point are almost smaller than their respective equivalent normal mean values and increase with the
increase of $P$. They tend to the equivalent normal mean values when $P_f = 50\%$. For some values of $P$, $c^*$ slightly exceeds the mean. This may be explained by the counter clockwise rotation of the critical dispersion ellipse due to the negative correlation (cf. Youssef Abdel Massih and Soubra 2008). Finally, the resistance factors $F_c$ and $F_\phi$ decrease with the increase of $P$ and become equal to 1 when $P_f = 50\%$ except in the case of $F_c$ in Table 1. In this case, $F_c$ first decreases and then increases with $P$. It becomes equal to 1 when $P_f = 50\%$. This trend is again due to the negative correlation between the shear strength parameters. Notice that $F_c$ and $F_\phi$ corresponding to different values of the reliability index are determined rigourously based on the maximization of the failure probability. Thus, they may be recommended for use in practice.

**Effect of the probability distribution and correlation of the input parameters on the reliability index**

Figure 2 shows the variation of the reliability index with the punching safety factor for the cases of *normal* and *non-normal* variables with or without correlation when the eccentricity ratio $e/B$ is equal to 0.3.

![Graph 1](image1)

**FIG. 2: Effect of the probability distribution and correlation of the input parameters on the reliability index**

![Graph 2](image2)

**FIG. 3: Effect of the variability of the random variables on the failure probability**

The reliability index corresponding to uncorrelated shear strength parameters is smaller than the one of negatively correlated variables for both normal and non-normal probability distributions. However, the probability distribution has a non-significant effect on the reliability index.
Effect of the variability of each random variable on the reliability index

Figure 3 shows the FORM failure probability versus the coefficient of variation of \( c \) and \( \phi \). For each curve, the coefficient of variation of a parameter is held to the same constant value given in the introduction of the section named "numerical results" and the coefficient of variation of the second parameter is varied over the range 5\%-30\%. The results show that the failure probability is highly influenced by the coefficient of variation of the angle of internal friction, the greater the scatter in \( \phi \), the higher the failure probability of the foundation. This means that the accurate determination of the distribution of this parameter is very important in obtaining reliable probabilistic results. The significant influence of \( \phi \) on \( P_t \) may be explained by the fact that a significant change in the deterministic ultimate bearing capacity is obtained due to a small change in \( \phi \); the cohesion parameter does not have a significant effect on the ultimate load.

Probabilistic design

The conventional deterministic approach used in the design of a shallow foundation consists in prescribing a target safety factor (generally \( F_p = 3 \) for the punching mode) and determining the corresponding breadth of the footing \( B \). In this section, a probabilistic design is presented. It consists in the calculation of \( B \) for a target reliability index of 3.8 as suggested by Eurocode 7 for the ultimate limit states. The mean value of the vertical applied load was taken equal to \( P = 800 \) kN/m and the eccentricity ratio was taken equal to 0.3. Figure 4 presents the probabilistic foundation breadth for different values of the coefficients of variation of the random variables and for different values of their coefficient of correlation. The cases of normal and non-normal variables are considered. This figure also presents the deterministic breadth corresponding to a punching safety factor of 3.

From figure 4, one can notice that the probabilistic foundation breadth decreases with the increase of the negative correlation between the shear strength parameters and the decrease of the coefficients of variation of the random variables. It can become smaller than the deterministic breadth for the common values of the soil variability (i.e. \( COV_\phi = 5\%-10\%, COV_c = 20\%, -0.7 \leq \rho_{c,\phi} \leq -0.3 \)). For large values of the coefficients of variation and small correlation coefficient, the probabilistic breadth is higher than the deterministic one. As a conclusion, the deterministic footing breadth may overestimate or underestimate the probabilistic one according to the values of the uncertainties. Contrary to Eurocode 7 which prescribes constant values of the resistance and load factors, the present Reliability Based Design RBD has the advantage of providing different values of these factors depending on the soil variability. These factors are the optimal ones and are determined rigorously by a maximization of the failure probability for a given soil variability.
CONCLUSION

This paper presents a reliability-based approach for the analysis and design of a strip footing subjected to an eccentric load. The random variables are the soil shear strength parameters. A RBD of the footing has also been presented. It was shown that the negative correlation between the shear strength parameters gives a higher reliability of the footing. However, the type of the probability distribution of the random variables does not have a significant effect on the reliability index. The failure probability was found to be significantly influenced by the coefficient of variation of $\phi$. The values of the design points have given information about the resistance factors of the random variables. The RBD has shown that the probabilistic foundation breadth decreases with the increase of the negative correlation between the shear strength parameters and the decrease of the coefficients of variation of the random variables. The deterministic footing breadth corresponding to a punching safety factor of 3 may thus overestimate or underestimate the probabilistic one according to the values of the uncertainties.
