Immersion and Invariance vs Sliding Mode Control for Reference Trajectory Tracking of Autonomous Vehicles

Gilles Tagne, Reine Talj and Ali Charara

Abstract—This paper focuses on the lateral control of intelligent vehicles. The aim is to minimize the lateral displacement of the autonomous vehicle with respect to a given reference trajectory. We present design and validation of two vehicle lateral controllers. The first controller based on higher-order sliding mode control (SMC) has been developed in [1]. The second controller is based on Immersion and Invariance (*I&I*) principle. Given the implicit resemblance between the SMC and the *I&I* principle, the comparison allows us to highlight the advantages and disadvantages of each control strategy for robust lane keeping for intelligent vehicles. To validate the control strategies, the closed-loop system has been simulated on Matlab-Simulink has been made using the experimental data acquired on the vehicle DYNA of Heudiasyc laboratory, a Peugeot 308, according to several real driving scenarios. The validation shows robustness and performances of each control approach, and puts in evidence the improvement brought by the *I&I* controller.

I. INTRODUCTION

The development of Advanced Driver Assistance Systems (ADAS) and autonomous driving has been favored by technological advances in recent years. Three main steps are necessary to ensure an autonomous navigation: the perception-localization, the path planning and the vehicle control. The vehicle control can be divided into two tasks: longitudinal control and lateral control. This paper focuses on the lateral control of intelligent vehicles. This is a very active research field that has been studied since the 1950s.

Lateral control consists on handling the vehicle using the steering wheel to follow the reference trajectory. Given the high nonlinearity of the vehicle on one hand, and the uncertainties and disturbances in automotive applications on the other hand, a very important issue to be considered in the control design is the robustness. The controller should be able to reject disturbances and deal with parameter uncertainties and variations. For example, in [2], a recent presentation of Junior; Stanford's autonomous research vehicle (the second at the DARPA Urban Challenge) is made for the purpose of ensuring robust autonomous driving.

In recent years, considerable research has been made to provide lateral guidance of autonomous vehicles. In literature, many control strategies have been developed. Simple

PID controllers have been proposed in [3] and [4]. We also have nested one in [5]. Moreover, other classical techniques have been used. We can cite H_∞ [6], state feedback [7], Lyapunov stability based control [8], fuzzy logic [9], fuzzy Takagi-Sugeno LQ [10], linear quadratic optimal predictive control [11], backstepping based approach [12] and many others. On the other hand, Model Predictive Control (MPC) appears to be well suited to the trajectory following [2], [13]. In [14] and [1], Sliding Mode Control (SMC) has been applied to the lateral control. This robust control strategy is well suited to driving applications, given its robustness against uncertainties and its capacity to reject disturbances. However, its main drawback is the chattering.

A variety of different vehicle controllers was proposed for trajectory tracking. Most of the works published previously do not compare their results with other approaches. Unfortunately, comparisons between existing control concepts are very rare. In [15], a comparison was made between proportional, adaptive, H_∞ and fuzzy controllers. More recently, in [16], a comparison of two controllers for trajectory tracking emergency was performed. In [17], continuous-time and discrete-time switched H_∞ were compared. It is therefore difficult to make an objective classification from the literature but different results showed clearly that the class of adaptive controllers represents a very promising technique for such uncertain and nonlinear application.

In [1], we have developed a controller based on higher-order sliding mode control. Given the implicit resemblance between the sliding mode controller and the *I&I* principle, for the purpose of designing nonlinear and adaptive controllers, a controller based on the *I&I* approach is developed for a comparative study.

The *I&I* principle is a relatively new method for designing nonlinear and adaptive controllers. The method relies upon the notions of system immersion and manifold invariance. The basic idea of the *I&I* approach is to achieve the control objective by immersing the plant dynamics into a (possibly lower-order) target system that captures the desired behavior [18]. This is achieved by finding a manifold in state-space that can be rendered invariant and attractive; with internal dynamics that reflect the desired closed-loop dynamics and by designing a control law that takes the state of the system towards the manifold. In others words, the *I&I* theory consists of defining a target dynamics and to design a control law that renders the manifold of the target dynamics attractive and invariant. Indeed, the *I&I* reformulation of the stabilization problem is implicit in sliding mode control, where the target dynamics are the

dynamics of the system on the sliding surface, which is made attractive by a discontinuous control law.

II. DYNAMIC MODELS OF VEHICLE

In this work, we use two vehicle models. To design the controller, a simple and widely used dynamic bicycle model [7] is considered (see Fig. 1).

Fig. 1. Bicycle model

This model is used to represent the lateral vehicle behavior and assumes that the vehicle is symmetrical, and tire sideslip angles on the same axle are equal. The roll and pitch dynamics are neglected and angles are assumed to be small (steering, sideslip, yaw). With a linear tire force model we obtain a Linear Parameter Varying (LPV) model, where the longitudinal velocity V_x is considered as a varying parameter. Dynamic equations in terms of sideslip angle and yaw rate of the bicycle model are given by:

$$\begin{cases} \dot{\beta} = -\frac{(C_f+C_r)}{mV_x}\beta - (1+\frac{L_fC_f-L_rC_r}{mV_x^2})\dot{\psi} + \frac{C_f}{mV_x}\delta \\ \dot{\psi} = -\frac{L_fC_f-L_rC_r}{I_z}\beta - \frac{L_f^2C_f+L_r^2C_r}{I_zV_x}\dot{\psi} + \frac{L_fC_f}{I_z}\delta \end{cases} \quad (1)$$

where β , ψ and δ represent respectively the sideslip angle, the yaw angle of the vehicle and the steering wheel angle (control input). Table I presents the vehicle parameters and nomenclature.

To validate in simulation the proposed controllers in closed-loop, we used a more representative model, namely

¹CERAM -"Centre d'Essais et de Recherche Automobile de Mortefontaine" is an automobile testing and research center located in France.

TABLE I
VEHICLE PARAMETERS AND NOMENCLATURE (BICYCLE MODEL)

V_x	Longitudinal velocity	-	[m/s]
β	Sideslip angle	-	[rad]
$\dot{\psi}$	Yaw rate	-	[rad/s]
δ	Steering wheel angle	-	[rad]
m	Mass	1719	[kg]
I_z	Yaw moment of inertia	3300	[kgm ²]
L_f	Front axle-COG distance	1.195	[m]
L_r	Rear axle-COG distance	1.513	[m]
C_f	Cornering stiffness of the front tire	170550	[N/rad]
C_r	Cornering stiffness of the rear tire	137844	[N/rad]

the 4-wheel model to represent the behavior of the vehicle and Dugoff's tire model for longitudinal and lateral tire forces.

III. CONTROL PROBLEM DEFINITION

The aim of the lateral control of autonomous intelligent vehicles is to minimize the lateral displacement of the vehicle with respect to a given reference path. The lateral error dynamics at the center of gravity of the vehicle, with respect to a reference path, is given by $\ddot{e} = a_y - a_{y_{ref}}$; where a_y and $a_{y_{ref}}$ represent respectively the lateral acceleration of the vehicle, and the desired one on the reference path. Assuming that the desired lateral acceleration can be written as $a_{y_{ref}} = V_x^2 \rho$, where ρ is the curvature of the road and given that $a_y = V_x(\dot{\beta} + \dot{\psi})$ [7], one can find:

$$\ddot{e} = V_x(\dot{\beta} + \dot{\psi}) - V_x^2 \rho \quad (2)$$

Replacing $\dot{\beta}$ by its expression in equation (1), we obtain:

$$\ddot{e} = -\frac{C_f + C_r}{m}\beta - \frac{L_f C_f - L_r C_r}{mV_x}\psi - V_x^2 \rho + \frac{C_f}{m}\delta \quad (3)$$

The new system state variables are $x = (\beta, \dot{\psi}, \dot{e}, e)^\top$, corresponding to the sideslip angle, the yaw rate, the lateral error and its derivative. The system has the following dynamics:

$$\dot{x} = Ax + B_1\delta + B_2\rho \quad (4)$$

where,

$$A = \begin{bmatrix} -\frac{(C_f+C_r)}{mV_x} & -1 - \frac{(L_f C_f - L_r C_r)}{mV_x^2} & 0 & 0 \\ -\frac{(L_f C_f - L_r C_r)}{I_z} & -\frac{(L_f^2 C_f + L_r^2 C_r)}{I_z V_x} & 0 & 0 \\ -\frac{(C_f+C_r)}{m} & -\frac{(L_f C_f - L_r C_r)}{mV_x} & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \quad (5)$$

The aim of the lateral control is to cancel the lateral displacement error. Then, for a given curvature ρ and longitudinal velocity V_L , the desired behavior corresponds to $\dot{e} = e = 0$. Hence, it is easy to prove that the desired equilibrium point is [7]:

$$(\beta, \psi, \dot{e}, e)^\top = (\beta^*, \psi^*, 0, 0)^\top$$

with

$$\begin{aligned}\beta^* &= (L_r - \frac{L_f m V_x^2}{C_r(L_f + L_r)})\rho \\ \psi^* &= V_x \rho\end{aligned}\quad (6)$$

At the equilibrium point, the control input is:

$$\delta^* = (L_f + L_r)\rho + \frac{m V_x^2 (L_r C_r - L_f C_f)}{C_f C_r (L_f + L_r)}\rho \quad (7)$$

We define the new error variables:

$$\begin{cases} \tilde{\beta} = \beta - \beta^* \\ \tilde{\psi} = \psi - \psi^* \\ \tilde{\delta} = \delta - \delta^* \end{cases} \quad (8)$$

Hence, the error dynamics of the system (4) having the origin as equilibrium point $(\tilde{\beta}, \tilde{\psi}, \tilde{\delta}, e)^\top = (0, 0, 0, 0)^\top$ become:

$$\dot{\tilde{x}} = A\tilde{x} + B_1\tilde{\delta} \quad (9)$$

where, A and B_1 have been defined above (5).

IV. SMC AND I&I CONTROLLERS DESIGN

After a brief presentation of the SMC controller, we will present the design of the I&I controller.

A. SMC controller

The SMC has been developed since 1950s and is recognized as one of the most promising techniques for robust control. The principle of SMC is to constrain the system trajectories to reach in finite time and remain on a sliding surface. However, its main drawback is the chattering. In this subsection, we recall the main lines of the design of the SMC controller. We used the super-twisting algorithm to minimize the lateral displacement. For more details, see [1].

The objective is to cancel the lateral displacement error. To this end, choosing the sliding variable s as follows:

$$s = \dot{e} + \lambda e \quad (10)$$

we obtain: $\dot{s} = \ddot{e} + \lambda \dot{e}$. Replacing $\ddot{e}$ by its expression (3), we obtain:

$$\dot{s} = -\frac{C_f + C_r}{m}\beta - \frac{L_f C_f - L_r C_r}{m V_x} \dot{\psi} - V_x^2 \rho + \frac{C_f}{m} \delta + \lambda \dot{e} \quad (11)$$

The variable s has a relative degree $r = 1$ with respect to the input δ . We can write $\dot{s}$, of the form:

$$\dot{s}(t, s) = \phi(t, s) + \varphi(t, s)\delta \quad (12)$$

with,

$$\begin{cases} \phi(t, s) = -\frac{C_f + C_r}{m}\beta - \frac{L_f C_f - L_r C_r}{m V_x} \dot{\psi} - V_x^2 \rho + \lambda \dot{e} \\ \varphi(t, s) = \frac{C_f}{m} \end{cases} \quad (13)$$

It is assumed that there exist positive constants $s_0, b_{\min}, b_{\max}, C_0$ such that $\forall x \in \mathbb{R}^n$ and $|s(t, x)| < s_0$, the system satisfies the following conditions:

$$\begin{cases} |\delta| \leq \delta_{\max} \\ 0 < b_{\min} \leq |\varphi(t, s)| \leq b_{\max} \\ |\phi(t, s)| < C_0 \end{cases} \quad (14)$$

So, the SMC algorithm based on super-twisting is given by:

$$\delta_{ST} = \delta_1 + \delta_2 \begin{cases} \delta_1 = -\alpha_1 |s|^{1/2} \text{sign}(s) \\ \dot{\delta}_2 = -\alpha_2 \text{sign}(s) \end{cases} \quad (15)$$

with α_1 and α_2 positive constants. The finite time convergence to the sliding surface is guaranteed for all:

$$\begin{cases} \alpha_2 > \frac{C_0}{b_{\min}} \\ \alpha_1 \geq \sqrt{\frac{4C_0(b_{\max}\alpha_2 + C_0)}{b_{\min}^2(b_{\min}\alpha_2 - C_0)}} \end{cases} \quad (16)$$

To avoid important peaks in transient phases, we add an equivalent command δ_{eq} obtained by solving the equation $\dot{s} = 0$. This term has the role of a feedforward that brings the system near to the sliding surface, and is given by:

$$\delta_{eq} = -\frac{m}{C_f} \phi(t, s) \quad (17)$$

Hence, the steering angle representing the control input of the system is defined as follows:

$$\delta_{SMC} = \delta_{ST} + \delta_{eq} \quad (18)$$

B. I&I controller

The principle of the I&I consists to achieving the control objective by immersing the system into a target dynamics that ensures the objective of the command. To design the I&I controller, some assumptions should be verified: the system and the target dynamics should both have their equilibrium at the origin respectively. The immersion of the system is achieved by an attractive and invariant manifold. So, the command consists on bringing the system state to the manifold. Astolfi et al. [18] presents the main stabilization result of the Immersion and Invariance method.

Now consider the vehicle lateral dynamical model (9). As mentioned before, the main objective of the steering controller is to cancel the lateral error displacement with respect to a given trajectory, i.e. $e = \dot{e} = 0$ at the equilibrium.

The target system is consequently chosen to be the image of the system (9) when $e = \dot{e} = 0$. More precisely, the target state vector is (ξ_1, ξ_2) , where ξ_1 and ξ_2 represent $\tilde{\beta}$ and $\tilde{\psi}$ respectively, when $e = \dot{e} = 0$. Note that for $e = \dot{e} = 0$, we also have $\ddot{e} = 0$. The dynamics can be expressed as follows,

$$\begin{bmatrix} \dot{\xi}_1 \\ \dot{\xi}_2 \end{bmatrix} = \begin{bmatrix} 0 & -1 \\ \frac{C_r(L_f + L_r)}{I_z} & -\frac{L_r C_r(L_f + L_r)}{I_z V_x} \end{bmatrix} \begin{bmatrix} \xi_1 \\ \xi_2 \end{bmatrix} \quad (19)$$

Proposition 1: The target model (19) has a globally asymptotically stable equilibrium at the origin $(0, 0)$.

Proof: The dynamics of the state vector $\xi = [\xi_1, \xi_2]$ can be written in the form $\dot{\xi} = C\xi$, with

$$C = \begin{bmatrix} 0 & -1 \\ \frac{C_r(L_f + L_r)}{I_z} & -\frac{L_r C_r(L_f + L_r)}{I_z V_x} \end{bmatrix} \quad (20)$$

Then, after some simple calculations, we obtain:

$$\det(sI - C) = s^2 + \frac{L_r C_r(L_f + L_r)}{I_z V_x} s + \frac{C_r(L_f + L_r)}{I_z} \quad (21)$$

The matrix C verifies the Routh-Hurwitz stability criterion ($V_x > 0$), which yields to the desired result. ■

Proposition 2: Consider the system (9) having the equilibrium point at the origin. Moreover, the subsystem (19), which is the image of the system (9) for $e = \dot{e} = 0$, has a globally asymptotically stable equilibrium at the origin. Then, the system (9) is *I&I*-stabilisable with target dynamics (19).

Proof: We define now the off-the-manifold variable

$$z = \dot{e} + \lambda e, \quad \text{s.t. } \lambda > 0 \quad (22)$$

Note that we choose $z = s$, the sliding variable defined above for the design of the SMC controller.

We have to select a control input $\tilde{\delta}$ such that the trajectories of the closed-loop system are bounded and $z = \dot{e} + \lambda e$ converges to zero. Notice that, when $z \rightarrow 0$, e converges exponentially to zero with the rate of convergence λ , yielding to the desired result. There is a strong resemblance with the principle of SMC which is to constrain the system trajectories to reach in finite time and remain on a sliding surface s . In the SMC, the convergence in finite time is guaranteed by a special law (15) with respect to certain conditions (16). For the *I&I* controller, we choose an exponential convergence. To this end, let

$$\dot{z} = -Kz, \quad \text{with } K > 0. \quad (23)$$

where K represents the rate of exponential convergence of z to zero. Replacing $\dot{z}$ and z by their expressions in (23), and after some calculations, one can find that the corresponding control input has the following expression:

$$\tilde{\delta} = -\frac{m(K+\lambda)}{C_f} \dot{e} - \frac{mK\lambda}{C_f} e + \frac{C_f + C_r}{C_f} \tilde{\beta} + \frac{L_f C_f - L_r C_r}{C_f V_x} \tilde{\psi} \quad (24)$$

The closed-loop system becomes:

$$\begin{bmatrix} \dot{\tilde{\beta}} \\ \dot{\tilde{\psi}} \\ \dot{e} \\ \dot{e} \end{bmatrix} = \begin{bmatrix} \mathcal{A}_{11} & \mathcal{A}_{12} \\ \mathcal{A}_{21} & \mathcal{A}_{22} \end{bmatrix} \begin{bmatrix} \tilde{\beta} \\ \tilde{\psi} \\ e \\ e \end{bmatrix} \quad (25)$$

with,

$$\begin{aligned} \mathcal{A}_{11} &= \begin{bmatrix} 0 & -1 \\ \frac{C_r(L_f + L_r)}{I_z} & -\frac{L_r C_r(L_f + L_r)}{I_z V_x} \end{bmatrix} = C, \\ \mathcal{A}_{12} &= \begin{bmatrix} \frac{-(K+\lambda)}{V_x} & \frac{-K\lambda}{V_x} \\ -\frac{L_f m(K+\lambda)}{I_z} & -\frac{L_f mK\lambda}{I_z} \end{bmatrix}, \\ \mathcal{A}_{21} &= \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}, \\ \mathcal{A}_{22} &= \begin{bmatrix} -(K+\lambda) & -K\lambda \\ 1 & 0 \end{bmatrix}. \end{aligned}$$

The closed-loop system can be interpreted as the interconnection of two subsystems: S_1 with the state variables $(\tilde{\beta}$ and $\tilde{\psi})$, and S_2 (with the state variables $\dot{e}$ and e). Given that the interaction matrix $\mathcal{A}_{21}$ is identically zero, hence, the dynamics of the subsystem S_2 are independent of S_1 , and can be written as follows:

$$\begin{bmatrix} \ddot{e} \\ \dot{e} \end{bmatrix} = \begin{bmatrix} -(K+\lambda) & -K\lambda \\ 1 & 0 \end{bmatrix} \begin{bmatrix} \dot{e} \\ e \end{bmatrix} \quad (26)$$

The subsystem S_2 combines and represents the interactions between the dynamics of both off-the-manifold variables z and e , which ensure the convergence of e to zero.

Proposition 3: The subsystem S_2 has a globally asymptotically stable equilibrium at the origin $(0,0)$.

Proof: The dynamics of the state vector $\zeta = [\dot{e}, e]$ can be written in the form : $\dot{\zeta} = \mathcal{A}_{22}\zeta$. The matrix $\mathcal{A}_{22}$ verifies the Routh-Hurwitz stability criterion for all $\lambda > 0$ and $K > 0$, hence the attractivity of the manifold is ensured. Consequently, the rates of convergence K and λ of z and e respectively, have to be chosen based on other practical considerations related to the system. ■

The subsystem S_1 depends on S_2 via the matrix $\mathcal{A}_{12}$. Defining $\tilde{u} = (K+\lambda)\dot{e} + K\lambda e$, the subsystem S_1 in closed-loop has the form:

$$\begin{bmatrix} \dot{\tilde{\beta}} \\ \dot{\tilde{\psi}} \end{bmatrix} = C \begin{bmatrix} \tilde{\beta} \\ \tilde{\psi} \end{bmatrix} + \begin{bmatrix} -\frac{1}{V_x} \\ -\frac{L_f m}{I_z} \end{bmatrix} \tilde{u} \quad (27)$$

Finally it is clear that when S_2 converges to $(0,0)$, the input $\tilde{u}$ of the subsystem S_1 converges to zero. Then, the system S_1 converges to the target dynamics (19), which is stable and converges to $(0,0)$. Indeed, we have proved previously that this target model has a globally asymptotically stable equilibrium at the origin $(0,0)$. So, the trajectories of the closed-loop system are bounded, yielding to the desired result. For more details on the proof of global asymptotic stability of the closed loop system, see [19], which presents that the cascade of Global Asymptotic Stable systems (GAS) with a bounded trajectory gives an global asymptotic stable system. In other words, GAS + GAS + bounded trajectory = GAS. ■

Stability of the system is assured with the proposed *I&I* controller for all its gains $\lambda > 0$ and $K > 0$. This is a very strong result that reveals some interesting characteristics of the system. Finally, the control input applied to the system (4) is:

$$\begin{aligned} \delta_{I\&I} = \tilde{\delta} + \delta^* &= -\frac{m(K+\lambda)}{C_f} \dot{e} - \frac{mK\lambda}{C_f} e + \frac{C_f + C_r}{C_f} \beta \\ &\quad + \frac{L_f C_f - L_r C_r}{C_f V_x} \psi + \frac{mV_x^2}{C_f} \rho \end{aligned} \quad (28)$$

The design of this controller allows us to prove that the stability of the controller is guaranteed for all positive gains. This result helps us to show certain characteristics of passivity of the system. These structural features of the system help to improve the design of the controller. Moreover, the response time of the controller is entirely determined by the parameters K and λ , which is not the case for the SMC controller. Finally, the design of this controller guarantees robust stability and some a priori known performances (response time of the controller).

V. RESULTS

To validate our control laws, the used experimental data were acquired on the vehicle DYNA on the CERAM test circuits. This vehicle is equipped with different sensors or observers providing the dynamic variables of the vehicle and its traveled path. The simulations in closed-loop are

performed using the real data, as a reference with the full vehicle model. For the control laws, we used the gains $\lambda = 8$ and $K = 1$ for the $I\&I$ controller, and $\lambda = 8, \alpha_1 = 0.005, \alpha_2 = 0.002$ for the SMC controller, with the nominal vehicle parameters (see Table I).

Fig. 2. Experimental vehicle (DYNA)

A. Test of the controllers during normal driving with nominal parameters

In this test (Fig. 3), lateral acceleration is less than $4m/s^2$. Longitudinal velocity is almost constant ($13.5m/s$). Fig. 3 shows the reference path and the trajectories followed by the controlled vehicles, the longitudinal speed variations and the lateral error. We observe that both controllers can

Fig. 3. Longitudinal speed, trajectories and lateral error

ensure the convergence of the lateral error. After the transient periods (change in curvature of the road), the SMC controller converges to 0 while the $I\&I$ controller converges to a small but nonzero value. The convergence time of the SMC controller is lower than that of the $I\&I$ controller. Both controllers have maximum comparable errors and ensure trajectory tracking (variable curvature).

Several other tests were performed, including scenarios of driving at high speed as well as situations where there is a saturation of lateral forces. So, tests show the good performance of both control strategies during normal driving at high and varying speed for nominal parameters known.

B. Robustness of controllers to vehicle parameter uncertainties

As mentioned previously, one of the major challenges for trajectory tracking is the robustness of the controller. In this subsection, we evaluate the robustness of the controllers with respect to parametric uncertainties of the vehicle. It is important to note that the parametric uncertainties can be due to the fact that the parameters may vary, but are considered

to be fixed for the command, for example the mass of the vehicle.

It is difficult to estimate accurately the cornering stiffness of the tire. Moreover, this parameter varies greatly depending on the type of the road, the vertical load, the camber, etc. It is therefore important to assess the robustness of the controller over cornering stiffness variations. Fig. 4 presents lateral errors for different uncertainties on the value of the cornering stiffness for the previous test.

Fig. 4. Robustness against uncertainties of cornering stiffness

For uncertainties in the order of $+/-30\%$, on the value of cornering stiffness, both controllers are able to follow the path with acceptable errors. In other words, the controllers are able to track the trajectory with a road coefficient of friction of 0.7 (cornering stiffness proportional to road coefficient of friction). Therefore, the robustness of the controller against cornering stiffness variations implicitly allows us to evaluate the robustness with respect to an unknown road coefficient of friction.

For uncertainties in the order of 10% on the value of cornering stiffness or mass, the SMC controller have similar errors (to those of nominal conditions). With the $I\&I$ controller, the error depends on the value of the parametric uncertainty. Note that the value of the parameter uncertainty strongly influences the convergence time of the SMC controller. When parametric uncertainty exceeds a certain threshold, the convergence over time is not guaranteed, and the errors of the SMC controller increases with great rates (see Fig. 4, SMC $+/-30\%$).

To summarize, we observe that the SMC controller provided low and almost constant errors while the condition of convergence in finite time is satisfied. When parametric uncertainty exceeds a certain threshold, the convergence in finite time is not guaranteed, and the error increases with a very large rate. It is important to note that this threshold is not known a priori and depends on the parameters, variables of the system and the amplitudes of the noises in the data. By increasing the values of the SMC controller gains to ensure acceptable errors for large parametric variations, one obtains an excessive increase in the phenomenon of chattering. This has the effect of degrading the passenger comfort. Also, it is important to note that in practice it is limited by the

bandwidth of the steering actuator. In this validation, we use a steering actuator with a cut-off frequency of 10Hz. For reasons of comfort we could impose a lower frequency, which would have the effect of degrading the performance of the SMC.

With the $I\&I$ controller, the error depends on the value of the parametric uncertainty and remains acceptable even for large variations. We note that large variations in the parameters degrade the performance but stability is maintained. This clearly shows that we have a robust stability (not depending on the value of the parameters of the system). Finally, these results show robustness and performances of each control approach.

VI. CONCLUSION

In this paper, we have compared two controllers for trajectory tracking of an autonomous vehicle. The first controller is the higher order sliding mode and specifically the super-twisting algorithm. The second controller is based on the Immersion and Invariance principle. Given the great similarity between these two control strategies, we aimed to improving the sliding mode by using the Immersion and Invariance principle (reduction or elimination of chattering, reduction of the sensitivity to the dynamic of the actuator, greater taking into account of the model).

The design of both controllers has been presented. The SMC controller has shown better performance for small parameter variations, while the condition of convergence in finite time is satisfied. This condition depends on the value of the system parameters and noise. It is therefore difficult to tune this controller. The design of the $I\&I$ controller allowed us to prove that the stability of this controller is guaranteed for all positive gains ($\lambda > 0$ and $K > 0$). In addition, the response time of that controller is totally determined by the parameters K and λ . So, performance and tuning of this controller is easily determined. This controller is able to give acceptable errors for large parametric uncertainties and guarantees a comfortable ride (absence of chattering). Also it is more robust to perform emergency maneuvers (for example, big turns). It is clear that with a greater consideration of the model and the characteristics of passivity of the system, the control by $I\&I$ can greatly improve the performances for autonomous driving applications and ADAS.

Stability of the system is assured with the proposed $I\&I$ controller for all its gains $\lambda > 0$ and $K > 0$. This is a very strong result that reveals some interesting characteristics of the system. More deep and promising characteristics of the system are under study now by the authors. Moreover, we will also test these control laws on a semi-autonomous vehicle or robotized vehicle, in the laboratory Heudiasyc.
