Design of observers implemented over FlexRay networks

Wei Wang, Dragan Nešić and Romain Postoyan

Abstract—We investigate the observer design for nonlinear systems whose measurements are sent over a network governed by FlexRay. FlexRay is a communication protocol used in the automotive industry which has the feature to switch between two scheduling rules associated with the two segments of its communication cycles. The objective of this paper is to generalize existing works on emulated observers for networked control systems (NCS) to be applicable to NCS with FlexRay. We propose for that purpose a novel hybrid model and guarantee the observer convergence provided that, for each segment, the scheduling rules are uniformly globally exponentially stable and the maximal allowable transmission intervals satisfy given explicit bounds. The analysis relies on the use of an hybrid Lyapunov function we recently constructed to investigate the stabilization of NCS with FlexRay. We finally apply the approach to a class of globally Lipschitz systems, which includes linear time-invariant systems as a particular case.

I. INTRODUCTION

Networked control systems (NCS) are characterized by the use of a shared serial communication channel to connect spatially distributed sensors and actuators with the control unit. The communication links have some advantages but introduce communication constraints which may have a severe impact on the desired performance requirements. In this paper, we address the observer design problem for NCS and we concentrate on the effect of time-varying data sampling and scheduling. The feature of our work is that we consider FlexRay protocol [2], which switches between two scheduling rules. Because of these switches, related available results on the observer design for NCS in [9], [10], [11] are not applicable and we need to solve nontrivial issues in terms of modeling and analysis. Our motivation to study NCS with FlexRay is justified by the fact that this communication protocol is increasingly used in the automotive industry and estimation methods for such systems are currently missing in the literature. A few works on the other hand analyze stability of NCS with FlexRay, see [6], [12] for instance.

We design the observer using the emulation approach like in [9], [10], [11]. The basic idea is to first synthesize the observer while ignoring the communication constraints.

Then, the observer is implemented over the network and conditions on the latter are derived to preserve the convergence properties of the observer. The emulation approach is advantageous as it allows us to use various available observer design tools for continuous-time systems. As mentioned above, the related results in [9], [10], [11] cannot be used when considering protocols with switching scheduling rules such as FlexRay [2].

The problem is modeled as a hybrid system using the formalism of [3], for which a jump either describes a transmission or a segment switch. The proposed NCS model is different from the one in [12] because our target is estimation and not stabilization. We consider static and dynamic segments of any given lengths for which transmissions are governed by uniformly globally exponentially stable (UGES) protocols, which cover the round robin (RR) and the try-once-discard (TOD) protocols as particular cases, see [7]. Employing a Lyapunov function we recently constructed to study stabilization of the NCS with FlexRay in [12], we ensure that the estimation error asymptotically converges to the origin provided the MATIs of each segment satisfy a given explicit bound and by appropriately emulating the observer. The obtained results are shown to be applicable to a class of globally Lipschitz systems which includes linear time invariant systems as a special case and for which these results are new.

The paper is organized as follows. We state the problem in Section II. The observer emulation is explained in Section III. The protocol model and the hybrid model for NCS are respectively presented in Sections IV and V. We study the convergence properties of the emulated observer in Section VI. A case study is given in Section VII. Conclusions and possible future works directions are provided in Section VIII.

II. PROBLEM STATEMENT

Notation. Let $\mathbb{Z}_{>0} := \{1, 2, \cdots \}$, $\mathbb{Z}_{\geq 0} := \{0, 1, 2, \cdots \}$ and $\mathbb{R}_{\geq 0} := [0, \infty)$. The Euclidean norm of a vector or a matrix is denoted by $\cdot$ and $\lambda_{\min}(P)$, $\lambda_{\max}(P)$ respectively stand for the minimum and maximum eigenvalues of a real symmetric positive definite matrix $P$. Given a closed set $A \subset \mathbb{R}^n$ and $x \in \mathbb{R}^n$, we define the distance of a vector $x$ to $A$ as $|x|_A := \inf_{y \in A} |x-y|$. A set-valued mapping $M : \mathbb{R}^m \rightrightarrows \mathbb{R}^n$ is outer semi-continuous (OSC) if and only if its graph $\{(y, z) : y \in \mathbb{R}^m, z \in M(y)\}$ is closed, see Lemma 5.10 in [3]. For $x \in \mathbb{R}^n$ and $y \in \mathbb{R}^m$, the notation $(x, y)$ denotes $[x^T, y^T]^T$.

A. Objective

Consider the nonlinear plant model

$$x_{k+1} = f(x_k) + Bu_k + w_k,$$

where $x_k$ is the state vector, $u_k$ is the control input, $w_k$ is the zero-mean Gaussian white noise with covariance $Q$, and $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a nonlinear function. The goal is to design an observer that estimates the state $x_k$ based on the measurement $y_k$. The observer is modeled as

$$\hat{x}_{k+1} = \hat{f}(\hat{x}_k) + B\hat{u}_k + \hat{w}_k,$$

where $\hat{x}_k$ is the estimate of $x_k$, $\hat{w}_k$ is the estimation error, and $\hat{f} : \mathbb{R}^n \rightarrow \mathbb{R}^n$ is an observer function. The observer is implemented over the network and the communication constraints are taken into account.

\[
\dot{x} = f(x) \quad y = g(x),
\]
where \( x \in \mathbb{R}^{n_x} \) is the state and \( y \in \mathbb{R}^{n_y} \) is the output. We assume that we know an observer of the form
\[
\dot{\hat{x}} = f(\hat{x}) + k(\hat{x}, y - \bar{y}) \quad \bar{y} = g(\hat{x}),
\]
where \( \hat{x} \in \mathbb{R}^{n_x} \) is the estimate of the state \( x \) and \( \bar{y} \in \mathbb{R}^{n_y} \) is the output to the observer. The observer (2) is designed such that \( x - \hat{x} \) globally asymptotically converges to zero.

Our objective is to propose an emulation implementation method to preserve the convergence properties of the observer under the communication constraints induced by the network. We provide a brief description of FlexRay and specify the properties of the transmission instants sequence \( \{t_i\} \in \mathbb{Z}_{>0} \) in the remaining part of this section.

### B. FlexRay

We briefly present FlexRay and the assumptions we make on the network; further details can be found in Section III in [12]. FlexRay is characterized by pre-set communication cycles of length \( T > 0 \), see [2]. Each cycle contains a static segment, a dynamic segment and two protocol segments called symbol window and network idle time, which are of respective lengths \( T_1, T_2, T_3, T_4 > 0 \), as shown in Figure 2. The lengths of the protocol segments are often negligible with respect to the lengths of the static and dynamic segments, we therefore ignore these.

Distinct network access techniques are applied for the static and the dynamic segments [2], [4], [8]. The static segment consists of time slots of equal length and it relies on a time division multiple access (TDMA) approach, where a single node is chosen by a static protocol and its packet is sent over the communication channel at the beginning of each time slot. The dynamic segment on the other hand employs the flexible time division multiple access (FTDMA) technique [1], which enables nodes to compete for accessing the network and a dynamic protocol can be implemented to select nodes to transmit messages based on the online information. The dynamic segment is composed of minislots, which are substantially shorter than static time slots and do not necessarily correspond to the transmission of a packet. The node with highest priority is assigned with the ‘earliest’ minislot and the minislots are idle when no nodes compete for access.

Let \( t_i^m \), \( j \in \mathbb{Z}_{>0} \) denote the segments switching instants. Let a packet be sent at transmission instant \( t_i^s \) and received at a reception instant \( t_i^r \) for \( i \in \mathbb{Z}_{>0} \), as illustrated in Figure 2. For modeling purposes, we assume that FlexRay cycles start with the static segment without loss of generality and that the following properties hold.

**Assumption 1 ([12]):**

(a) The lengths of the symbol window and the network idle time are negligible, i.e. \( T_3 = T_4 = 0 \).

(b) Data are transmitted instantaneously, i.e. \( t_i := t_i^s = t_i^r \) for all \( i \in \mathbb{Z}_{>0} \).

![Observer implemented on FlexRay](image1)

**Fig. 1.** Observer implemented on FlexRay

![FlexRay Communication Cycle](image2)

**Fig. 2.** FlexRay Communication Cycle [12]
(c) Data coding time is negligible and a transmission occurs at the beginning of the two segments.

(d) The static time slots are of length $\tau_{MATI,1} > 0$ and each inter-transmission time interval in the dynamic segments, denoted by $\tau_{dy,i}$, satisfies $\tau_{dy,i} \in [\varepsilon, \tau_{MATI,2}]$ for all $i \in \mathbb{Z}_{>0}$, where $\varepsilon > 0$ refers to the length of a minislot.

Let $\tau_{MATI,1} > 0$ be such that $T_1 = N \tau_{MATI,1}$ for some $N \in \mathbb{Z}$. Under Assumption 1, it is shown in [12] that for any given $T_1, T_2 > 0$ the transmission instants sequence $\{t_i\}_{i \in \mathbb{Z}_{>0}}$ satisfies

$$t_{i+1} - t_i = \tau_{MATI,1} \quad \forall i \in \mathbb{Z}_{>0},$$

$$(t_{2n+1} - t_{2n}) \in [t_{2n-1}, t_{2n+1}^m]$$

where $n \in \mathbb{Z}_{>0}$ and the segment switching instants sequence $\{t_{2n}^m\}_{n \in \mathbb{Z}_{>0}}$ satisfies $t_{2n-1} - t_{2n-2} = T_1$ and $t_{2n+1} - t_{2n} = T_2$.

III. OBSERVER EMULATION

We emulate the observer (2) as follows

$$\dot{x} = f(x) + k(x, \tilde{y} - y).$$

The emulated observer (7) no longer depends on $y$, but on $\tilde{y}$ because of the effect of the network. Furthermore, it does not depend on its own output $\tilde{y}$ but on $y$. The designed variable $\tilde{y}$ can be interpreted as an artificially introduced networked version of $y$ (see [11]), as will be clear below.

Let $\tilde{y} = (\tilde{y}_1, \cdots, \tilde{y}_\ell)$ and $\tilde{y} = (\bar{y}_1, \cdots, \bar{y}_\ell)$. The dynamics of $\tilde{y}$ is given by

$$\frac{\dot{\tilde{y}}}{\tilde{y}} = \tilde{y} \quad t \in [t_i, t_{i+1}],$$

$$\tilde{y} = \tilde{y}_j(t_i) \quad \text{if} \quad \dot{\tilde{y}}_j(t_i) = y_j(t_i).$$

In that way, $\tilde{y}_j$ evolves along the same vector field as $y_j$ between two successive transmission instants, and is reset to $\tilde{y}_j$ when the corresponding node is updated.

Let $e_o := \tilde{y} - y \in \mathbb{R}^{n_y}$ denote the (artificially introduced) network-induced error on the observer output, $e_p := \tilde{y} - y \in \mathbb{R}^{n_y}$ be the network-induced error on the plant output, $n_e := n_y$. In that way, (7) becomes

$$\dot{x} = f(x) + k(x, y - \tilde{y} - e).$$

where $e := e_o - e_p$ is the network-induced error we study in the present paper.

Remark 1: If we implement (7) with $\tilde{y}$ instead of $\bar{y}$, (9) turns into

$$\dot{x} = f(x) + k(x, y - \tilde{y} + e_p).$$

In this case, it is in general not possible to preserve the asymptotic convergence of the observer when zero-order-hold devices are used to generate $\tilde{y}$, since the error $e_p$ is a priori non-vanishing as $e_p = \tilde{y}$ between two transmission instants and $\bar{y}$ is in general different from zero. Only a practical convergence may be guaranteed, see [9]. This issue is overcome with (7), as we show in Section VI.

Between the two successive transmission instants, the implementation of the observer leads to

$$\dot{e} = g_e(x, \bar{x}, e),$$

$$\dot{e}_p = g_p(x, \bar{x}, e_p), \quad t \in [t_i, t_{i+1}],$$

where $i \in \mathbb{Z}_{>0}$, $g_e(x, \bar{x}, e) := \frac{\partial f}{\partial x}(\bar{x})f(x) - \frac{\partial k}{\partial x}(\bar{x})(f(x) + k(x, g(x) - g(x) - e))$ and $g_p(x, \bar{x}, e_p) := f(\bar{g}(x) + e_p, \bar{x}) - \frac{\partial g}{\partial x}(x)f(x)$. Note that the relevant network-induced error is $e$ not $e_p$ (in view of (9)) and the dynamics of $e$ during inter-transmission time intervals does not depend on the holding functions $f$. Consequently, for the constructed $\tilde{y}$ in (7) which determines the dynamics of $e$, different observer implementations make no difference to our main results. This is an important difference with [9], noting that the results in [9] can be viewed as a particular case of the present paper in the absence of perturbations.

The dynamics of the network-induced errors at transmission instants is governed by scheduling rules. We investigate this aspect in the following section.

IV. PROTOCOL MODEL

A. Model

At the transmission instant $t_i$, $i \in \mathbb{Z}_{>0}$, if the node $j$ has accessed to the network, it holds that, in view of (3), (8) and the fact that $y(t_{i+1}) = y(t_j)$ and $\tilde{y}(t_{i+1}) = \tilde{y}(t_j)$ (since $y$ and $\tilde{y}$ are not affected by transmissions),

$$e_{pj}(t_{i+1}) = \bar{y}_j(t_{i+1}) - y_j(t_i) = 0$$

for $j \in \{1, \cdots, \ell\}$, and

$$e_{ok}(t_{i+1}) = \bar{y}_k(t_{i+1}) - y_k(t_i) = e_{ok}(t_i)$$

for $k \in \{1, \cdots, \ell\}$ satisfying $k \neq j$. Following the terminology of [7], we call the equation given below that specifies how $e_p$ at transmission times $t_i$ is mapped at $t_{i+1}$ as the protocol equation

$$e_p(t_{i+1}) = h_p(i, e(t_i), e_p(t_i), q(t_i)),$$

where $q : \mathbb{R} \to \{1, 2\}$ is a switching signal indicating which segment is active: $e(t) = 1$ denotes the static segment and $q(t) = 2$ represents the dynamic segment, for $t \geq 0$. The mapping $h_p$, which is allowed to depend on both $e_p$ and $e$, has the form of

$$h_p(i, e(t_i), e_p(t_i), q(t_i)) := (2 - q(t_i))h_{p,1}(i, e(t_i), e_p(t_i)) + (q(t_i) - 1)h_{p,2}(i, e(t_i), e_p(t_i)),$$

where $h_{p,1}$ and $h_{p,2}$ respectively denote the scheduling rule corresponding to the static and the dynamical segment.

On the other hand, considering the definition of $e$ and the case when the $j$-th node is selected, we have that

$$e_j(t_{i+1}) = (\bar{y}_j(t_{i+1}) - \bar{y}_j(t_i)) - (\bar{y}_j(t_i) - y_j(t_i)) = 0$$

and

$$e_k(t_{i+1}) = (\bar{y}_k(t_{i+1}) - \bar{y}_k(t_i)) - (\bar{y}_k(t_i) + y_k(t_i)) = e_k(t_i)$$

This comes from the fact that the time slots in the static segment are of equal length.
hold for $j, k \in \{1, \ldots, \ell\}$ satisfying $k \neq j$. With the mapping $h_e$ to specify how $e$ evolves at each transmission instant, we write (15) as $e(t^+_t) = h_e(i, e(t), e_p(t), q(t))$, which can also be formed as (14) with $h_{e,1}$ and $h_{e,2}$ denoting the scheduling rules corresponding to the static and dynamic segments. An example is given below on the construction of $h_e$.

In view of (11), (12) and (15), we see that the $e$-subsystem is strongly related with the $e_p$-subsystem at transmission instants. It is shown in Section VII of [11], that the $e$-subsystem inherits the stability property of the $e_p$-subsystem at jumps, under mild conditions. This will be important in Section VI when we study the stability of the overall system. We next present an example of protocols which are compatible with FlexRay.

B. Example

The RR protocol can be used to govern the static segment. It grants access to the nodes in a periodic fashion. In view of [7], $h_{p,1}$ is defined by, for $e_p \in \mathbb{R}^{n_e}$ and $i \in \mathbb{Z}_{>0}$,

$$h_{p,1}(i, e_p) := (I - \Delta(i))e_p,$$

where $\Delta(i) =$ diag$\{\tilde{\delta}_1(i)I_{n_1}, \ldots, \tilde{\delta}_\ell(i)I_{n_\ell}\}$, $I_{n_i}$ is the identity matrix of dimension $n_i$, with $\sum_{i=1}^\ell n_i = n_e$. $\tilde{\delta}_s$ satisfies $\tilde{\delta}_s(i) = 1$ when $s - 1 = i \bmod \ell$ and $\tilde{\delta}_s(i) = 0$ otherwise, for $s \in \{1, \ldots, \ell\}$ and $i \in \mathbb{Z}_{>0}$.

We consider a TOD-like protocol for the dynamic segment, which grants access to the node where $e_j$ (not $e_p$) is the biggest. Hence, the function $h_{p,2}$ is defined as ([7]),

$$h_{p,2}(e, e_p) := (I - \Psi(e))e,$$

with $\Psi(e) =$ diag$\{\psi_1(e)I_{n_1}, \psi_2(e)I_{n_2}, \ldots, \psi_\ell(e)I_{n_\ell}\}$. The function $\psi_s$ satisfies $\psi_s(e) = 1$ when $s = \min(\arg\max_{j \in \{1, \ldots, \ell\}}|e_j|)$ and $\psi_s(e) = 0$ otherwise, for $s \in \{1, \ldots, \ell\}$ and $i \in \mathbb{Z}_{>0}$.

Now, we derive the definitions of $h_{e,1}$ and $h_{e,2}$. From (11), (12) and (15), we see that the $e$-subsystem has the same dynamical property as the $e_p$-subsystem at transmission instants: its $j$-th component resets to zero and other components keep unchanged when the $j$-th node is chosen. Consequently, in view of (16) and (17), for any $e \in \mathbb{R}^{n_e}$,

$$h_{e,1}(i, e) = (I - \Delta(i))e,$$

$$h_{e,2}(e) = (I - \Psi(e))e,$$

where $\Delta$ and $\Psi$ are defined above.

Remark 2: Note that the TOD protocol above requires the use of smart sensors that have sufficient computational capacities to run a copy of the observer located in the $(\ell + 1)$-th node. That is, at each node $j \in \{1, \ldots, \ell+1\}$, an observer is run as

$$\dot{x}_j^i = f(x_j^i) + k(x_j^i, y - \bar{y})$$

with $\bar{y}$ given in (8). They are synchronized, i.e. $x^i_j(t) = x^k_j(t)$ for all $t$ and $j, k \in \{1, \ldots, \ell+1\}$, by assuming that $x^i_j$ and $x^k_j$ start with the same initial condition. Thanks to the assignment algorithm $\sigma$ (recall the algorithm of $\sigma$ above equation (3)), the available information of the $j$-th node for $j \in \{1, \ldots, \ell\}$ and $t \in [t_1, t_{i+1}]$ is given as below.

1) The $j$-th (sensor) node: $\sigma(t), y_{s(t)}(t), y_j(t), \bar{x}_j^i(t)$.

2) The $(\ell + 1)$-th (passive) node: $\sigma(t), y_{s(t)}(t), \bar{x}_{\ell+1}^i(t)$.

Since each node receives $y_{s(t)}(t)$ and then the same input signal $\bar{y}$, and they are synchronized for all time (unless a computational glitch occurs) and the convergence property analysis reduces to studying a single observer.

V. NCS MODEL

We now implement the observer over the network and model the overall dynamics as a hybrid system using the formalism of [3]. We introduce for this purpose two clock variables $\tau_1, \tau_2 \in \mathbb{R}_{\geq 0}$ like in [12]. The variable $\tau_1$ represents the time elapsed since the last transmission and $\tau_2$ denotes the time elapsed since the last segment switch. We also introduce $\kappa \in \mathbb{Z}_{\geq 0}$ to count the number of transmissions. Let $\upsilon := (\xi, x)$, $n_\upsilon := n_x + n_2$ and $\varphi := (e, e_p, \kappa, \tau_1, \tau_2, q)$, where $\xi := x - \bar{x} \in \mathbb{R}^{n_x}$ with $n_x = n_2$ is the observation error. Then, the following hybrid system is obtained.

$$
\begin{align*}
\dot{\upsilon} &= F_e(\upsilon, \varphi), \\
\varphi^+ &= G(\varphi), \\
(\upsilon, \varphi^+) &\in \mathcal{E}_0 \cup \mathcal{E}_1 \cup \mathcal{E}_2.
\end{align*}
$$

The flow set $\mathcal{E}_0$ and the jump set $D$ are defined based on the conditions of Assumption 1. In particular, the definition of $C$ means that system (19) is allowed to flow in the static segment $(q = 1)$ when $\tau_1 \leq \tau_{MAT1,1}$ and in the dynamic segment $(q = 2)$ when $\tau_1 \leq \tau_{MAT2,1}$. The system experiences a jump, which corresponds to a transmission when $\tau_1 = \tau_{MAT1,1}$ and $\tau_2 < \tau_1$ for $q = 1$, and when $\tau_1 \in [\tau_{MAT1,2}, \tau_{MAT2,1}]$ and $\tau_2 < \tau_1$ for $q = 2$. The other kind of jumps correspond to the segment switches, which happen at $\tau_2 = \tau_1$ when $q = 1$ and $\tau_2 = \tau_2$ when $q = 2$. The transmissions are assumed to occur at the beginning of the two segments, i.e., when $\tau_1 \in [\tau_{MAT1,2}, \tau_{MAT2,1}]$ at the beginning of the static segments, where the lower bound $\varepsilon$ is the minislot length (see item (d) of Assumption 1), and when $\tau_1 = \tau_{MAT1,1}$ at the beginning of the dynamic segment.

The flow mappings $F_e$ and $G$ have the following form $F_e(\upsilon, \varphi) := [f^e_\xi(\upsilon, e), f^e_\zeta(\upsilon, e)]^T$, $F(\upsilon, \varphi) := [g^e_\xi(\upsilon, e), g^e_\zeta(\upsilon, e)]^T$. The vector fields $g_\xi$ and $g_\zeta$ come from (10) and the expressions of $f_\xi$ and $f_\zeta$ are obtained by direct calculations from (1) and (2). Note that, thanks to (7), the continuous vector fields $g_\xi$, $f_\xi$ and $f_\zeta$ are independent to the variable $e_p$. The jump mapping $G$ is defined as

$$G(\varphi) := \begin{cases} G_1(\varphi) & \varphi \in \Omega_1, \\
G_2(\varphi) & \varphi \in \Omega_2, \\
\{G_1(\varphi), G_2(\varphi)\} & \varphi \in \Omega_3. \end{cases}$$
with \( G_1(\varphi) := \left[h_e^T(\kappa, e, e_p, q) h_p^T(\kappa, e, e_p, q) \kappa + 1 \tau_2 q\right]^T \), \( G_2(\varphi) := \left[e_e^T e_p \kappa \tau_1 0 3 - q\right]^T \) and \( \Omega_i := \mathbb{R}^{2n_i} \times \mathbb{Z}_{\geq 0} \times \Omega_i \), where \( \Omega_i \) for \( i \in \{1, 2, 3\} \) are given by
\[
\begin{align*}
\Omega_1 &:= \left((\{(\text{MATI,1}) \times \{0, T_1\}) \cup (\{(e, \text{MATI,2}) \times \{0\})\} \times \{1\}\right) \cup \left((\{(e, \text{MATI,2}) \times \{0, T_2\}) \cup (\{(\text{MATI,1}) \times \{0\})\} \times \{2\}\right) \\
\Omega_2 &:= \{(0, \text{MATI,1}) \times \{T_1 \} \times \{1\}\} \cup (\{(e, \text{MATI,2}) \times \{T_2 \} \times \{2\}\) \\
\Omega_3 &:= \{(\text{MATI,1}) \times \{T_1 \} \times \{1\}\} \cup (\{(e, \text{MATI,2}) \times \{T_2 \} \times \{2\}\).
\end{align*}
\]
(21)

The jump map \( G \) is defined on the set \( D (\Omega_1 \cup \Omega_2 \cup \Omega_3 = D) \) and is OSC. Hence, noting that \( G \) is locally bounded relative to \( D \), flow maps \( F_v \) and \( F_e \) are continuous and the sets \( C \) and \( D \) are closed, we have that the hybrid system (19) is well-posed, see Chapter 6 in [3] for more detail.

### VI. MAIN RESULTS

We assume that the scheduling rules which govern the transmissions of the static and the dynamic segments satisfy the properties listed below.

**Assumption 2:** For each \( m \in \{1, 2\} \), there exist \( W_m : \mathbb{R}^{n_v} \times \mathbb{Z}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0} \), which is locally Lipschitz in its first argument, a continuous function \( h_m : \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0} \), constants \( a_{W_m} \), \( \omega_{W_m} \), \( \gamma_m \geq 0 \) and \( \rho_m \in (0, 1) \) such that for any \( \kappa \in \mathbb{Z}_{\geq 0} \) and \( e, p \in \mathbb{R}^{n_e} \),

1. \( a_{W_m} \leq W_m(e, \kappa) \leq \omega_{W_m} \),
2. \( W_m(h_m(e, \kappa, e_p, m), \kappa + 1) \leq \rho_m W_m(e, \kappa) \),
3. \( \langle \frac{\partial W_m(e, \kappa)}{\partial e}, g_e(v, e) \rangle \leq L_m W_m(e, \kappa) + H_m(v) \).

Items 1)-2) of Assumption 2 mean that the \( e \)-subsystem at jumps is UGES. Item 3) implies that an exponential growth condition of the \( e \)-subsystem holds during two consecutive transmissions. Using the same technique as Section VII of [11], we can show that items 1)-2) of Assumption 2 are valid for example for the RR-TOD protocol in Section IV-B. Item 3) of Assumption 2 is verified when \( g_e \) is globally Lipschitz, vanishes at the origin and \( \partial W_m/\partial e \) is bounded, which is the case for RR and TOD protocols in view of Section V in [7]. We next assume that the observer has been designed such that the following conditions hold.

**Assumption 3:** There exist a continuously differentiable function \( V : \mathbb{R}^{n_c} \rightarrow \mathbb{R}_{\geq 0} \) and \( \nabla V : \mathbb{R}^{n_c} \rightarrow \mathbb{R}^{n_c} \) such that for each \( m \in \{1, 2\} \) there exist a positive definite continuous function \( q_m \) and \( \gamma_m \geq 0 \) such that for all \( v \in \mathbb{R}^{n_e}, e \in \mathbb{R}^{n_v} \) and \( \kappa \in \mathbb{Z}_{\geq 0} \),

1. \( q_m(\|\xi\|) \leq V(\xi) \leq \gamma_m(\|\xi\|) \),
2. \( (\nabla V(\xi), \frac{e}{e_p}(v, e) \leq -q_m(\|\xi\|) - \rho_m(\|\xi\|) - H_m(\xi) + \gamma^2_m W^2_m(e, \kappa) \),

where the functions \( W_m \) and \( H_m \) come from Assumption 2.

We show later in Section VII that these conditions are satisfied by a class of high-gain observers.

We next provide explicit bounds on the constants \( \tau_{\text{MATI,1}} \) and \( \tau_{\text{MATI,2}} \). We first introduce some notations for the ease of presentation. Let \( \rho_m \in (0, 1) \) and \( \gamma_m \geq 0 \) come from Assumptions 2 and 3, \( \pi_m := \frac{\pi_{W_3-m}}{\pi_{W_m}} \) and
\[
c_m(s) := \frac{\gamma_m}{\gamma_m/k_m - d_m(s)} + \Delta_m + 1 \rho_m s
\]
(22)
where \( \Delta_m := \left(\frac{M_1}{\rho_m}\right) \), \( d_m(s) := \frac{k_m - \gamma_m}{k_m - \gamma_m \rho_m} \), for \( s \geq 0 \) with \( M := \max \{1, 2\pi \rho_1, 3\pi \rho_2, 2\pi \rho_3, 2\pi \rho_4\} \) and \( k_m := \max \{\gamma_m, \frac{\gamma^2_m}{\gamma_3 - \rho_3 m}\} \). Note that \( c_m(s) \) is strictly positive since it decreases when \( s \) grows and \( c_m(s) \rightarrow k_m + \Delta_m > 0 \) when \( s \rightarrow \infty \).

**Assumption 4:** For each \( T_1, T_2 > 0 \),
\[
\tau_{\text{MATI,1}} = \frac{T_1}{T_1 / \tau_{\text{MATI,1}}} \quad \tau_{\text{MATI,2}} = \tau_{\text{MATI,2}}.
\]
(23)
where, for \( m \in \{1, 2\} \),
\[
\tau_{\text{MATI,1}} = \frac{1}{L_m \rho_m(T_m) \arctan(\lambda(T_m))} \quad \tau_{\text{MATI,2}} = \frac{L_m}{\rho_m(T_m) \arctan(\lambda(T_m))}
\]
(24)
where \( L_m, \gamma_m > 0 \) and \( \rho_m \in (0, 1) \) coming from Assumptions 2 and 3, \( \lambda(s) := \frac{r_m(s)}{2e}\gamma_m \rho_m(1-\rho_m) + \rho_m \), \( r_m(s) := \sqrt{\gamma_m c_m(s) - 1} \) and \( c_m : \mathbb{R}_{>0} \rightarrow \mathbb{R}_{>0} \) given by (22).

Recall that the time slots in the static segment are of equal length. The first equation in (23) is justified since \( T_1 \) has to be a multiple of \( \tau_{\text{MATI,1}} \) (see Section II-B). Compared with the MATI in Section VIII in [11], where the observer design problem is considered for NCS scheduled by non-switched protocols, the MATIs in (23) adapt to the segment lengths and the latter can be arbitrarily selected. The smaller \( T_m \) the smaller \( \tau_{\text{MATI,1}} \). On the other hand, when \( T_1 \) goes to infinity, which corresponds to the case where there is only one segment, we recover the MATI bounds in [11] by taking \( M = 1 \) and \( k_1 = \gamma_1 \), which is possible since we can choose parameters \( \gamma_2, \pi_1, \pi_2, \rho_2 \) in an arbitrary way as the segment \( q = 2 \) will never be activated.

For the ease of presentation, we write system (19) as
\[
\begin{align*}
\dot{\zeta} &= \mathcal{F}(\zeta) \\
\dot{\zeta}^+ &\in \mathcal{G}(\zeta) \\
\zeta &\in \mathcal{C} \\
\zeta^+ &\in \mathcal{D}
\end{align*}
\]
(25)
where \( \zeta := (v, \varphi), C := \mathbb{R}_{>0} \times \mathbb{C}, D := \mathbb{R}_{>0} \times \mathbb{D}, \mathcal{F}(\zeta) := (F_v(v, \varphi), F_e(v, \varphi)) \) and \( \mathcal{G}(\zeta) := (v, G(\varphi)) \).

It should be emphasized that, because we implement the observer as in (7) and because we have selected the coordinates in (19), we can apply the results of [12] to study the stability of system (25). In particular, we can construct the hybrid Lyapunov function below
\[
U(\zeta) := V(\xi) + \gamma_1 \phi_1(\eta_1) \eta_2(\eta_2) W_1^2(e, \kappa)(2 - q) + \gamma_2 \phi_2(\eta_1) \eta_2(\eta_2) W_2^2(e, \kappa)(q - 1),
\]
(26)
where \( \theta_1, \theta_2, \phi_1 \) and \( \phi_2 \) are appropriately designed functions such that \( U \) is positive definite on the set \( \mathcal{C} \cup \mathcal{D} \), decreases during flow and does not increase at jumps, see [12] for more
details. With such $U$, we can derive the following result. The proof is omitted as it follows from Proposition 1 and Theorem 1 in [12].

**Theorem 1:** Suppose that Assumptions 2-4 hold for system (25) and let $A := \{\xi : \xi = 0, e = 0\}$. Then, there exists $\beta \in K\mathcal{L}$ such that all solutions $\xi$ to system (25) satisfy

$$\|\xi(t, j)\|_{A} \leq \beta(\|\xi(0, 0)\|_{A}, t + j), \quad \forall (t, j) \in \Omega_{c}.$$  \hspace{1cm} (27)

\[\square\]

### VII. Case study

Consider the nonlinear system

$$\dot{x} = Ax + \eta(x), \quad y = Cx$$  \hspace{1cm} (28)

where $x \in \mathbb{R}^{n_x}$, $y \in \mathbb{R}^{n_y}$, $A$, $B$ and $C$ are constant matrices of appropriate dimensions, and the vector field $\eta : \mathbb{R}^{n_x} \rightarrow \mathbb{R}^{n_x}$ is globally Lipschitz with a Lipschitz constant $M \geq 0$.

We consider an observer of the form

$$\dot{\hat{x}} = A\hat{x} + \eta(\hat{x}) + k(y - \bar{y}), \quad \bar{y} = C\hat{x}$$  \hspace{1cm} (29)

where $k$ is a matrix to be designed. Suppose that the measurements of $y$ are transmitted to the network through $\ell$ nodes for some $\ell \in \mathbb{Z}_{>0}$ and the matrix $k$ is such that the following condition holds.

**Assumption 5:** There exists a real symmetric positive definite matrix $P$ such that $V : \xi \rightarrow \xi^{T}P\xi$ and $\frac{\partial V}{\partial \xi}(A - kC)\xi + \eta(x) - \eta(x - \xi) \leq -cV$ for all $x, \xi \in \mathbb{R}^{n_x}$ and some $c > \max\{a_{1}^{2}, a_{2}^{2}\}$, where $\xi := x - \hat{x}$, $a_{1} := \sqrt{t}(|C(A - kC)| + |M|C|), a_{2} := |C(A - kC)| + |M|C|$.\[\square\]

Assumption 5 holds for any detectable linear time-invariant systems and is satisfied by the high-gain observers in [5]. We now implement the observer (29) over FlexRay as explained in Section III with the transmissions being scheduled by the RR-TOD protocol presented in Section IV-B. The emulated observer has form of

$$\dot{\hat{x}} = A\hat{x} + \eta(\hat{x}) + k(\bar{y} - \hat{y})$$

with $\bar{y}$ being defined as (8). We can rewrite the obtained system into (19) with $h_{c}$, $h_{p}$ defined by (16)-(18), and, for any $x, \xi \in \mathbb{R}^{n_x}$ and $e \in \mathbb{R}^{n_y}$,

$$f_{\xi}(\xi, x, e) := (A - kC)\xi + \eta(x) - \eta(x - \xi) + ke,$$

$$g_{\xi}(\xi, x, e) := C(A - kC)\xi + C(\eta(x) - \eta(x - \xi)) + Cke,$$

$$g_{p}(\xi, x, ep) := \bar{f}(C(x + ep, x - \xi) - C(Ax + \eta(x))).$$

We next verify Assumptions 2 and 3 provided that Assumption 5 holds. We present the conclusion in the following proposition. The proof is omitted due to space limitations.

**Proposition 1:** Consider system (19) with $h_{c}$, $h_{p}$ defined by (16)-(18), $f_{\xi}$, $f_{x}$, $g_{\xi}$ and $g_{p}$ given above, and suppose Assumption 5 holds. Then, there exist $W_{1}$ and $W_{2} : \mathbb{R}^{n_y} \times \mathbb{Z}_{>0} \rightarrow \mathbb{R}_{\geq 0}$ such that Assumptions 2 and 3 hold with the $V : \mathbb{R}^{n_x} \rightarrow \mathbb{R}_{\geq 0}$ defined as Assumption 5, constants

$$\alpha_{W_{1}} = 1, \quad \alpha_{W_{2}} = \sqrt{t}, \quad L_{1} = |Ck|, \quad L_{2} = \sqrt{\tau}Ck,$$

for $H_{1}(\xi) := a_{1}|\xi|$, $L_{2} = |Ck|$ for $H_{2}(\xi) := a_{2}|\xi|$ for all $\xi \in \mathbb{R}^{n_x}$, $\gamma_{1} = \sqrt{\tau}Ck^{2} + \nu$ and $\gamma_{2} = \sqrt{\tau}Ck^{2} + \nu$ for an arbitrary $\nu > 0$, where $a_{1}$ and $a_{2} \geq 0$ come from Assumption 5.\[\square\]

Note that all parameters needed to calculate MATI bounds $\tau_{MATI,1}$ and $\tau_{MATI,2}$ are given in Proposition 1. For any given length $T_{1}$ and $T_{2}$, we can calculate $\tau_{MATI,1}$ and $\tau_{MATI,2}$ using Assumption 4 and Theorem 1 shows that the observation error $\xi$ and the network induced error $e$ globally asymptotically converges to the origin.

### VIII. Conclusion

We have proposed a method to design emulated observer for nonlinear networked control systems with FlexRay. We have generalized prior results on the observer emulation for NCS in [11] to be applicable for FlexRay networks. A novel hybrid model has been proposed for that purpose, with which we showed that the observer convergence to zero is ensured provided that, for each segment, the scheduling rules are uniformly globally exponentially stable and the maximal allowable transmission interval satisfy given explicit bounds. The analysis relies on the use of an hybrid Lyapunov function we recently constructed to investigate the stabilization of NCS with FlexRay. In future work, we will consider the case where the measurements are noisy and where the plant dynamics depend on some external inputs.
