ABSTRACT
We present a novel approach for parallelizing the execution of queries over XML documents, implemented within our system PAXQuery. We compile a rich subset of XQuery into plans expressed in the PArallelization ConTracts (PACT) programming model. These plans are then optimized and executed in parallel by the Stratosphere system. We demonstrate the efficiency and scalability of our approach through experiments on hundreds of GB of XML data.

Design, Performance, Experimentation

1. INTRODUCTION
Increasingly large data volumes have lead to the appearance of massively parallel processing frameworks, such as MapReduce [7]. Its main advantage is to simplify parallel data processing and handle task allocation and fault tolerance transparently from the application.

While the simplicity of MapReduce is an advantage, it is also a limitation, since large data processing tasks are represented by complex programs consisting of many Map and Reduce tasks. In particular, since these tasks are conceptually very simple, one often needs to write programs comprising many successive tasks, which limits parallelism. To overcome this problem, more powerful abstractions have appeared to express massively parallel complex data processing, such as the Parallelization Contracts programming model [2] (or PACT, in short).

In a nutshell, PACT generalizes MapReduce by (i) manipulating records with any number of fields, instead of (key, value) pairs, (ii) enabling the definition of custom parallel operators by means of second-order functions, and (iii) allowing one parallel operator to receive as input the outputs of several other such operators. The PACT model is part of the open-source Stratosphere platform [18].

In this work, we present PAXQuery, a massively parallel XQuery processor. Given a very large collection of XML documents, evaluating a query that navigates over these documents and also joins results from different documents raises performance challenges, which may be addressed by parallelism. Inspired by other high-level data analytics languages that are compiled into parallel frameworks [3, 10, 16], PAXQuery translates XML queries into PACT plans. The main advantage of this approach is implicit parallelism: neither the application nor the user need to partition the XML input or the query across nodes. This contrasts with prior work [4, 12]. Further, we can rely on the Stratosphere platform for the optimization of the PACT plan and its automatic transformation into a data flow that is evaluated in parallel on top of the Hadoop Distributed File System (HDFS); these steps are explained in [2].

In the sequel, Section 2 describes PAXQuery architecture and main features in detail, and provides a beginning-to-end query translation example. Section 3 describes the experimental evaluation of our system. Section 4 discusses related work and Section 5 concludes.

2. PAXQUERY ARCHITECTURE
Our approach for implicit parallel evaluation of XML queries is to translate them into PACT plans as depicted in Figure 1. The central vertical stack traces the query translation steps from the top to the bottom, while at the right of each step we show the data models manipulated by that step. We present each step of the translation below.

2.1 Query language
PAXQuery supports a representative subset of XQuery [19], the W3C’s standard query language for XML data, which has been recently enhanced with strongly requested features geared towards XML analytics. In particular, our
goal was to cover (i) the main navigational mechanisms of XQuery, and (ii) its key constructs to express analytical style queries e.g. aggregation, explicit grouping, and rich comparison predicates.

Example. The following XQuery extracts the name of users, and the items of their auctions (if any):

```xml
let $pc := collection('people')
let $cc := collection('closed_auctions')
for $p in $pc/site/people/person, $i in $p/@id
let $n := $p/name
return $n
```

The above query shows some of the main features of our XQuery fragment. It includes FLWR expressions, which are powerful enough to express complex operations like iterating over sequences, joining multiple documents, and performing grouping. XPath paths start from the root of each document in a collection of XML documents, or from the bindings of a previously introduced variable: we support the XPath 

\[
\text{let } $pc := \text{collection('people')},
\text{let } $cc := \text{collection('closed_auctions')},
\text{for } $p in $pc/site/people/person, $i in $p/@id
\] 

```
let $n := $p/name
return $n
```

Our approach is based on the representation of the XQuery query as an equivalent algebraic expression, on which multiple optimizations can be applied. XQuery translation into different algebra formalisms and the optimization of resulting expressions have been extensively studied \[5, 8, 17\].

A significant source of XQuery complexity comes from nesting: an XQuery expression can be nested in almost any position within another. In particular, nested queries challenge the optimizer, as straightforward translation into nested plans leads to very poor performance. Effective optimization techniques translate nested XQuery into unnested plans relying on joining and grouping \[8, 13, 14\]. Depending on the query shape, such decorrelating joins may be nested and/or outer joins.

PAXQuery uses the algebra presented in \[13\], and translation from XQuery to this algebra is outlined in \[1\]. However, we can easily adapt to any XML query algebra used by existing engines that satisfies the following two assumptions: (i) the algebra is tuple-oriented (potentially using nested tuples), and (ii) the algebra is rich enough to support decorrelated (unnested) plans even for nested XQuery; in particular we consider that the query plan has been unnested \[14\] before we start translating it into PACT.

2.2 XML query algebra

Our approach is based on the representation of the XQuery query as an equivalent algebraic expression, on which multiple optimizations can be applied. XQuery translation into different algebra formalisms and the optimization of resulting expressions have been extensively studied \[5, 8, 17\].

A significant source of XQuery complexity comes from nesting: an XQuery expression can be nested in almost any position within another. In particular, nested queries challenge the optimizer, as straightforward translation into nested plans leads to very poor performance. Effective optimization techniques translate nested XQuery into unnested plans relying on joining and grouping \[8, 13, 14\]. Depending on the query shape, such decorrelating joins may be nested and/or outer joins.

PAXQuery uses the algebra presented in \[13\], and translation from XQuery to this algebra is outlined in \[1\]. However, we can easily adapt to any XML query algebra used by existing engines that satisfies the following two assumptions: (i) the algebra is tuple-oriented (potentially using nested tuples), and (ii) the algebra is rich enough to support decorrelated (unnested) plans even for nested XQuery; in particular we consider that the query plan has been unnested \[14\] before we start translating it into PACT.

2.3 Algebraic representation of XQuery

We introduce our algebraic representation of XQuery by the following example (see \[13\] for details):

Example (continuation). The algebra plan for the XQuery introduced above is shown in Figure 2. The schemas of the tuples produced by each operator are denoted by $S_i$. We discuss the operators starting from the leaves.

The XML `scan` operators take as input the `people` (respectively `closed_auctions`) collection of XML documents and create a tuple out of each document in the collection.

XQuery may perform `navigation`, which, in a nutshell, binds variables to the result of path traversals. Navigation is commonly represented through tree patterns, whose nodes carry the labels appearing in the paths, and where some target nodes are also annotated with names of variables to be bound, e.g. $p/pc$, $i$ etc. The algebra we consider allows for consolidating as many navigation operations from the same query as possible within a single navigation tree pattern, and in particular navigation performed outside of the for clauses. Large navigation patterns lead to more efficient query execution, since patterns can be matched very efficiently against XML documents \[6\]. Our algebra uses a navigation operator parameterized by an extended tree pattern (ETP) supporting multiple returning nodes, child and descendant axis, and nested and optional edges.

Consider the ETP $e_1$ in Figure 2. The operator navigation$_{e_1}$ concatenates each input tuple successively with all $id$ attributes (variable $i$) resulting from the embeddings of $e_1$ in the value bound to $pc$. The node labeled $name$ is (i) optional and (ii) nested with respect to its parent node $person$, since by XQuery semantics: (i) if a given $p$ lacks a name, $p$ still contributes to the query result; (ii) all names for a given $p$ are bound into a single sequence. Observe that all name elements (variable $n$) are nested into variable $t$, which did not appear in the original query; in fact, $t$ is created by the XQuery to algebra translation to hold the nested collection with all values bound to $n$. The operator navigation$_{e_2}$ is generated in a similar fashion. Therefore, in the previous query, ETPs $e_1$ and $e_2$ correspond to the following fragment:

```xml
let $n := $p/name
let $r := $i
for $c in $cc/closed_auction, $b in $c/buyer/person, $s in $c/seller/person
```

Above the navigation operators in Figure 2 we have a nested left outer join (nojoin$_{p}$) on a disjunctive predicate $p$, which brings together people and the auctions they participated in, either as buyers or sellers. Observe that as the join is outer, all people are kept in the output, even if they did not participate in any auction.

Finally, the XML construction (construct$_L$) is responsible for transforming a collection of tuples to XML. For each tuple in its input, construct$_L$ builds one XML tree for each construction tree pattern in the list $L$ attached to the operator. In our example, $L$ contains a single pattern that generates for each tuple an XML tree consisting of elements of the form `<res>{$n,$r}</res>`.
2.4 PACT model

The PACT model is a generalization of MapReduce, based on the concept of parallel data processing operators. PACT plans are DAGs of implicit parallel operators, that are optimized and translated into explicit parallel data flows by Stratosphere.

Data model. PACT plans manipulate nested records of the form \( r = (f_1, f_2, \ldots, f_n) \) where \( 1 \leq k \leq n \). The first component \( f_1, f_2, \ldots, f_k \) is an ordered sequence of fields \( f_i \); in turn, a field \( f_i \) is either an atomic value (string) or a ordered sequence \( (r'_1, \ldots, r'_m) \) of records. The second component \( (i_1, i_2, \ldots, i_k) \) is an ordered, possibly empty, sequence of record positions in \( [1 \ldots n] \) indicating the key fields for the record. Each of the key fields must be an atomic value. The key of a record \( r \) is the concatenation of all the key fields \( f_1, f_2, \ldots, f_k \).

Processing model. Data sources and sinks are, respectively, the starting and terminal nodes of a PACT plan. The input data is stored in files; a function parameterizing the data source specifies how to structure the data into records. In turn, data is output into files, with the destination and format similarly controlled by an output function.

The rest of data processing nodes in a PACT plan are operators. An operator manipulates bags of records. Its semantics is defined by (i) a parallelization contract, which determines how input records are organized into groups; and (ii) a user function (or UF) that is executed independently over each bag (group) of records created by the parallelization contract (these executions can take place in parallel).

Although the PACT model allows creating custom parallelization contracts, a set of them for the most common cases is built-in: Map, Reduce, Cross, Match, and CoGroup (see Figure 3). The Map contract forms an individual group for every input record. The Reduce contract forms a group for every unique value of the key attribute in the input data set, and the group contains all records with that key value. The Cross, Match, and CoGroup contracts are used to define binary operators. The Cross contract forms a group from every pair of records in its two inputs (essentially, it produces the Cartesian product of the two input bags). The Match contract forms a group from every pair of records in its two inputs, only if the records have the same value for the key attribute. Finally, the CoGroup contract forms a group for every value of the key attribute (from the domains of both inputs), and places each record in the appropriate group depending on the key value of the record.

2.5 From algebra expressions to PACT plans

We describe now how PAXQuery translates XML algebraic expressions into PACT plans. First, out of nested tuples containing XML data instances (trees with identity), we create PACT nested records. Second, we translate XQuery algebraic expressions into PACT plans. Details about the former are omitted in this presentation, for space reason, while we focus in the latter.

Table 1 depicts the supported algebra operators and the contracts used by the PACT operators resulting from our translation. First, observe that the scan, respectively construct, functionality is integrated into a source, respectively sink, in the PACT plan. In turn, unary operators use Map and Reduce contracts depending on their semantics; the implementation of their UF s is in most of the cases straightforward. Finally, the translation of the binary operators is more complex, as they have to deal efficiently with the nested and/or outer nature of some joins, which may result in multiple operators at the PACT level. We illustrate this more elaborated translation with the following example.

Example (continuation). Consider the algebra plan in Figure 2. PAXQuery generates the PACT program shown in Figure 3 each \( K_i \) contains the positions of the key fields in records. The XML source operators scan (in parallel) the respective collections and transform each document into a
record. Next, the \texttt{Map} operators apply the \texttt{navigation} \texttt{UF} in parallel on the records thus obtained, following the query’s XPath expressions. The nested outer join is translated into two \texttt{CoGroup} operators and a \texttt{post-processing Reduce}. The core difficulty to address by our translation is to correctly express (i) the \textit{disjunction} in the \texttt{where} clause of the query, and (ii) the \texttt{outerjoin} semantics (recall that in this example a \texttt{<res>} element must be output even for people with no auctions). The main feature of the \texttt{nopostuf}(\(\rho^i, k\)) \texttt{UF} associated to each \texttt{CoGroup} is to guarantee that no erroneous duplicates are generated when the parallel evaluation of more than one conjunctive predicate is true for a certain record. The \texttt{Reduce} operator groups all the results of the previous \texttt{CoGroup} operators having the same left hand-side record, and then the \texttt{nopostuf} \texttt{UF} associated to it is applied to produce the final result for the join. Finally, the XML sink builds and returns XML results.

Clearly, complex joins such as the one contained in the example could be translated using a single \texttt{Cross} operator instead of multiple \texttt{CoGroup}. However, this would be less efficient and scale poorly (number of comparisons quadratic in the input size), as our experiments demonstrate.

### 2.6 Optimization and execution by Stratosphere

In the last step, PAXQuery sends the PACT plan to the Stratosphere platform, which optimizes it, and turns it into a data flow that is evaluated in parallel, as explained in [2].

### 3. IMPLEMENTATION AND EXPERIMENTS

PAXQuery has been implemented in Java 1.6, and it relies on the Stratosphere platform [18] for the execution. We present here some experimental results obtained with it.

PAXQuery scalability was studied by fixing a set of 14 queries, generating 11,000 documents (34GB) per node, and varying the number of nodes from 1 to 2, 4, 8 respectively; the total dataset size increases accordingly in a linear fashion, up to 272GB. Figure 5 (left) shows the response times for each query. Our results show that the translation to PACT allows PAXQuery to parallelize every query execution step with no effort required to partition, redistribute data etc., and thus to scale out with the number of machines in a cluster. The only case where scale-up was not so good is \texttt{q4} where we used a \texttt{Cross} to translate an inequality join; this highlights the interest of the more efficient operators (especially \texttt{CoGroup}) used in the other plans.

Figure 5 compares PAXQuery with XQuery processors in a centralized setting (one single node, 34 GB of data). None of the competing processors was able to evaluate any of our queries with joins across documents (\texttt{q6-q14}), as they run out of memory or out of time, highlighting the need for efficient parallel platforms for evaluating such queries on such large document collections.

### 4. RELATED WORK

MRQL [9] proposes a simple SQL-like XML query language implemented through a few operators directly compatible with XML query processors. MRQL queries may be nested, however, its dialect does not allow for expressing the rich join flavours that we use. Further, the XML navigation supported by MRQL is limited to XPath, in contrast to our richer navigation based on tree patterns with multiple returning nodes, and nested and optional edges. ChuQL [12] is an XQuery extension that exposes the MapReduce framework to the developer in order to distribute computations among XQuery engines; this leaves the parallelization work to the programmer, in contrast with our implicit query parallelization approach.

### 5. CONCLUSION AND FUTURE WORK

We have presented the PAXQuery approach for the implicit parallelization of XQuery through translation to PACT. Our experiments demonstrate the efficiency and scalability of PAXQuery. It is our plan to open-source the system in the near future. In the future, we contemplate the integration of indexing techniques into PAXQuery, and reusing intermediate results in the PACT framework to enable efficient multiple-query processing.
