Running head: Abundance of Nitrogen Cycling Microbes in Tidal Flats

Abbreviations:
AMB, anammox bacteria; amoA, ammonia monooxygenase gene; AOA, ammonia-oxidizing archaea; AOB, ammonia-oxidizing bacteria; C/N, ratio of carbon to nitrogen; DIN, dissolved inorganic nitrogen; DO, dissolved oxygen; LZB, Laizhou Bay; N₂, dinitrogen gas; NH₃, ammonia; NH₄⁺, ammonium; NH₄-N, ammonium nitrogen; nirK, gene encoding the copper-containing nitrite reductase; nirS, gene encoding the cytochrome cd₁-containing nitrite reductase; NO₂⁻, nitrite; N₂O, nitrous oxide; NO₂-N, nitrite-nitrogen; NO₃-N, nitrate-nitrogen; nosZ, gene encoding nitrous oxide reductase; rRNA, ribosomal RNA; psu, practical salinity units; qPCR, quantitative PCR; As, Arsenic; Co, cobalt; Cd, cadmium; Cr, chromium; Cu, copper; Ni, nickel; Pb, lead; Zn, zinc. Fe, iron; %Rₐₓₓ, percentage of N₂ production due to anammox.
Abstract

The relative abundances of nitrifying, denitrifying and anammox prokaryotes in sediments of three hypernutrified estuarine tidal flats of Laizhou Bay, Bohai Sea, China were investigated. Quantitative PCR estimates indicated that in most cases archaeal (AOA) *amoA* genes were more abundant than bacterial (AOB) *amoA* genes, and ratio of AOA/AOB was correlated with pH, Cd and Cu. Of the denitrifiers, *nirK*-type outnumbered *nirS*-type, with *nosZ*-type being the lowest. Variation of the ratio between *nirK* and *nirS* abundance depends on pH, nitrite, nitrate and Cd. The combination of (*nirS+nirK-nosZ*), an indicator of genetic potentials for N\textsubscript{2}O emission, was only related to the temperature. Anammox bacterial 16S rRNA gene abundances were correlated with salinity, pH, nitrite, and Cu. In contrast, the contribution of anammox to N\textsubscript{2} production, by using anammox bacterial 16S rRNA/*nosZ* ratio as a proxy, was correlated to temperature, ammonium and dissolved oxygen in the overlying water, ratio of organic carbon to nitrogen and arsenic in sediments. Our study stresses that abundances of N-cycling functional groups respond differently to variations of environmental conditions, and multiple factors including heavy metals with relatively low concentrations may play a role in shaping nitrogen cycling processes in these estuarine tidal flats.

**Keywords:** Environment factors; heavy metals; nitrogen cycle; community size; abundance; gene copy number ratio.
1 Introduction

A tidal flat is a multifunctional ecosystem characterized by high primary production, intense nutrient remineralization and pollutant transportation and transformation in sediments. In estuarine tidal flats, microbial processes play an important role in self-purification by transformation, degradation, and alleviation of these pollutant and nutrient overloads [1, 2]. Microorganism-mediated nitrogen cycling processes are of particular concern with respect to the ecosystem functions and services provided by estuaries [3] given that nitrogen limits primary oceanic production, and nitrogen overloading may be implicated in coastal eutrophication.

Nitrification, denitrification, and anaerobic ammonium oxidation (anammox) are tightly coupled nitrogen cycling processes in marine sediments, in which nearly 50% of marine nitrogen removal occurs [4]. Ammonia oxidation is the first and rate-limiting step of nitrification in which ammonia (NH$_3$) is oxidized to nitrite (NO$_2^-$) by ammonia-oxidizing archaea (AOA) and ammonia-oxidizing bacteria (AOB). The ammonia monoxygenase gene (amoA) has been used extensively as a molecular marker for studying both types of ammonia oxidizers in environmental samples [5, 15, 18-21, 33, 34, 37, 39, 40, 42-45]. Denitrification is an anaerobic reduction of nitrate, through nitrite and to nitrous oxide (N$_2$O) and eventually dinitrogen (N$_2$). Two functionally similar but structurally different genes, nirK and nirS, encoding the copper (NirK) and cytochrome cd1-containing nitrite reductase (NirS), have not been found in the same organism and show different distributions in environments [6]. Both nirK and nirS genes are responsible for the rate-limiting step (NO$_2^-$ to NO), and the nosZ gene codes for nitrous oxide reductase which catalyzes the reduction of N$_2$O to N$_2$, the final step of denitrification [7, 8]. Like denitrification, anammox represents a net loss of nitrogen from the system by the production of N$_2$ via the reduction of NO$_2^-$ coupled to the oxidation of ammonium (NH$_4^+$). Specific primers targeting 16S rRNA genes have been used for detecting anammox bacteria in environments [7].

It has been shown that community size or abundance of a functional community involved in nitrogen cycling is frequently correlated with the process rate, which reflects the ecosystem functions provided by the community [9-11]. For example, Hallin et al. (2009) found that abundance, rather than composition, correlated with denitrification rates and nitrification rates by ammonia-oxidizing archaea in agricultural soils [9]. Bacterial amoA gene abundance and ammonium content best explain potential nitrification rates in Alaskan soils [11], whereas nosZ, nirS and nirK gene abundance and nitrate best explain potential denitrification rates in estuarine sediments [12]. Denitrifying gene abundances can be used as proxies for predicting N$_2$O emissions in soil and wetland environments [10, 13]. A positive correlation between anammox cell number and activities was reported in both water columns and sediments, the abundance of anammox bacteria therefore can be considered as a proxy for anammox activities in environments [14-17].

Earlier studies of marine sediments from a variety of estuarine locations have shown different patterns of AOA/AOB dominance [18-21]. For denitrifying genes, nirS was more abundant than nirK in the San Francisco Bay estuary and subtropical Fitzroy estuary [21, 22]. The contribution of anammox to N$_2$ production was estimated to be relatively low in coastal environments, and dissolved oxygen, nutrient load
and salinity have been suggested as controls of the contribution of anammox to nitrogen removal [17, 23]. However, only a few studies have examined the abundances of ammonia oxidizers, different types of denitrifiers, and anammox bacteria in a single survey; and the genetic potential for N₂O emissions and contribution of anammox to N₂ production and their spatiotemporal pattern have seldom been explored for estuarine tidal flats.

Recent studies have showed that heavy metal accumulation may be an important factor in regulation of nitrogen transformations, because some critical enzymes involved in the microbial nitrogen cycle are metalloenzymes [24]. For example, the AMO coded by *amoA* gene is a Cu/Fe containing enzyme [25], and the NIR coded by *nirK* gene has been shown to contain Cu [26]. The effect of heavy metals on nitrogen cycling populations in sediments have not been studied sufficiently [22]. Moreover, most of the studies that have been performed have targeted only the top layer of sediments, and few have examined variability in N-cycling microbes’ distributions in deeper layers. Surprisingly, AOB 16S rRNA genes had been detected at depths of up to 40 cm in sediments, and rates of nitrification down to 8 cm depth were also detectable, whereas the depth distribution of AOA in estuarine sediments is largely unknown [27, 28]. Recently, it was also demonstrated that the greatest potential for anammox was localized to the upper 2 cm and could be detected down to a depth of 4.5 cm in the sediments [29].

In the past decades, the Laizhou Bay (LZB), Bohai Sea, northern China has been hypernutrified due to huge interrestrial input (most commonly, dissolved inorganic nitrogen, DIN) from about 20 rivers of the coastal zone [30, 31]. In the meantime, in order to supply more tideland for economic developments (e.g. aquaculture, industry, harbor construction) in the coastal-line region of southern bank of LZB, tidal flat reclamation projects have been extensively planned and will be implemented in the near future. Thus, the environmental and ecological impacts of these reclamation projects are of great concern. In this study, we aimed to provide a baseline examination of ecosystem functions provided by nitrogen cycling microbes in sediments of LZB estuarine tidal flats, by using the gene abundance as indicators. For this purpose, abundances of N-cycling gene markers (*amoA*, *nirS*, *nirK*, *nosZ* and anammox 16S rRNA) for ammonia oxidization, denitrification, and anammox processes were determined by quantitative PCR (qPCR). Copy number ratios of related genes and their relationship with environmental factors were calculated in order to explore the environmental impact on dominance of functional phylotypes, genetic potentials for N₂O emission, and contribution of anammox to N₂ production in coastal sediments. In addition, our study provides additional data for the links between microbial nitrogen cycle and trace metal levels.

### 2 Materials and Methods

#### 2.1 Study Sites and Sampling

Estuarine tidal flats of Bailang River (BL), Di River (Di) and Jiaolai River (JL), which flow into the Laizhou Bay (LZB), Bohai Sea, were investigated (Fig. 1). These three threes have different pollution history. The Bailang River is 127 km long and drains a catchment of about 1,237 km²; it used to receive a lot of sewage and industrial wastewater as it flowed through Weifang City. However, the execution of a
remediation project has significantly improved water quality of this river since 2006. The estuarine area covering three sampling sites (BL1-3) has been enclosed for mariculture since May 2011 and this led to less tidal exchange and higher salinity due to evaporation especially in summer. The Jiaolai River is about 130 km long, with a catchment area of 5478 km², receiving extensive agricultural and industrial discharges. The Di river is small sewage river (23 km long, catchment area 119 km²), loaded with a large amount of wastewater from dyeing and subsurface brine industries, resulting in relatively high alkalinity and salinity.

In each tidal flat (location), three sites (JL1-3, BL1-3 and Di1-3) located in lower tidal area were sampled (Fig. 1). Sediment samples were collected in November 2010 (winter) and August 2011 (summer). Sediment cores (7.5 cm internal diameter) were taken with a custom-made corer. The top/upper layer (0-2 cm) and the lower layer (2-5 cm) of sediments were sliced and put into sterile plastic bags. Samples were stored in an ice box (4°C) and immediately frozen at −80°C after transferred to the laboratory.

2.2 Analysis of Environmental Factors

Dissolved oxygen (DO), pH, salinity, and the temperature of overlying water were measured on site with a Hydrolab MS5 Water Quality probe (HACH, USA). Lyophilized sediments were leaching liquor with KCl (2M), then nitrate (NO₃⁻-N), nitrite (NO₂⁻-N), and ammonium (NH₄⁺-N) were measured with a nutrient AutoAnalyser (Seal, Germany). Total organic carbon and nitrogen contents of sediments were measured with a Vario Micro Cube Elemental Analyser (Elementar, Germany). A Marlvern Mastersizer 2000F granulometer (Malvern, England) was used for sediment grain size analysis. Sediments were treated with 1M HCl [32], and concentrations of eight heavy metals (As, Co, Cd, Cr, Cu, Ni, Pb and Zn) were determined with an ELAN DRC II plasma mass spectrometry (ICP-MS) (PerkinElmer, Hong Kong).

2.3 DNA Extraction and Quantitative PCR Assay

Total genomic DNA of the sediment samples was extracted using the UltraClean Soil DNA Isolation kit (MO-BIO, USA) according to the manufacturer’s instructions. To examine the spatiotemporal variation of community size of N-cycling groups in estuarine sediments, the abundances of several genes (anammox bacterial 16S rRNA, AOB-amoA, AOA-amoA, nirS, nirK and nosZ) were quantified using quantitative PCR (qPCR). Primers used were as listed in Table 1. Plasmids containing cloned gene PCR amplicons were extracted with the TIANpure Midi Plasmid Kit (Tiangen, Beijing, China) for use in standard curves: archaeal amoA clone AOALZB-1, bacterial amoA clone AOBLZB-8, anammox bacterial 16S rRNA clone AMX-LZB-11, nirS clone NIRSLZB-7, nirK clone NIRKLZB-3, and nosZ clone NOSZLZB-6. Concentrations of sediment and standard DNA were measured with a NanoDrop 2000C spectrophotometer (Thermo, Wilmington, DE, USA). A serial tenfold dilutions (10⁻² to 10⁻⁷) were used to obtain standard curves. All sample and standard reactions were performed in triplicate with an ABI 7500 Fast Real-time PCR System (Applied Biosystems, Foster City, CA, USA), and an average value was calculated. The quantification was based on the fluorescent dye SYBR Green I. Each reaction was performed in a 25 μl volume containing 1 μl of DNA template, 0.5 μl of each primer (10 μM) and 12.5 μl of Maxima
SYBR Green/ROX qPCR Master Mix 2x (Fermentas, USA). The PCR cycle started with 2 min at 50°C and 10 min at 95°C, followed by a total of 40 cycles of 30 s at 95°C, 40 s at 57°C for nirS genes (55°C for AMB 16S rRNA gene, 58°C for AOB-amoA and AOA-amoA genes, and 51°C for nirK gene), and 40 s at 72°C. Melt curves were obtained to check the specificity of amplification. The PCR amplification efficiencies were 85-113%, and correlation coefficients (R²) for all assays were more than 0.99.

2.4 Statistical analysis
Student’s t-test (two-tailed) was used to compare mean values of environmental variables as well as gene abundance between tidal flats, seasons, or layers. Spearman’s correlation coefficient (ρ) between microbial abundances and environmental variables were calculated. All these analyses were performed using the program SPSS 13.0 for windows (SPSS, Chicago, USA).

3 Results
3.1 Environmental Characteristics
Thirty-six sediment samples were taken from 2 layers, 9 sites in 2 seasons. Environmental factors during the samplings are shown in the Fig. S1. Water temperature ranged from 7.6°C to 33.7°C, with significant differences between winter (mean 10.8°C) and summer (mean 30.4°C) (t-test, P<0.01). Although the water salinity varied greatly from 11.1 psu (practical salinity units) to 50.3 psu, there was no statistically significant difference between the seasons or locations (P>0.05; Fig. S1). A similar situation occurred for other environmental factors such as pH (5.97 – 8.61), dissolved oxygen (228.1 – 361.3 μM), and nitrate (2.71 – 15.54 mg/kg), nitrite (0.03 – 2.37 mg/kg), ammonium (5.67 – 11.79 mg/kg), and ratio of organic carbon to organic nitrogen (C/N) (6.73 – 11.89), except that average concentrations of nitrate (4.52 mg/kg) and nitrite (0.21 mg/kg) in JL were significantly lower than those (12.19 and 0.82 mg/kg) in Di tidal flat.

The median sediment grain size ranged from 14.1 to 86.6 μm, with larger size in BL and Di, whereas there was no significant difference between seasons or layers. According to the three quality grades of marine sediments defined by the National Standard of China (NSC) GB18668-2002 [39], concentrations of heavy metals As (0.84-3.91mg/kg), Co (1.75-5.78 mg/kg), Cd (0.03-0.08 mg/kg), Cr (1.49-6.09 mg/kg), Cu (1.32-11.06 mg/kg), Ni (2.35-8.58 mg/kg), Pb (3.43-14.27 mg/kg) and Zn (5.05-14.05 mg/kg) in the sampling sites were lower than the first grade quality, representing a status of none to slight contamination. A previous study on surface sediments of LZB also showed similar levels of metal concentrations, which were lower than other coastal area in China (e.g. Jiaozhou Bay, Hongkong coast) and oversea (e.g. Thermaikos Gulf, Greece) [31]. Nevertheless, among the three tidal flats, JL generally had the most high levels of heavy metals. Significant differences in concentrations of Cd, Cu, Ni, Pb and Zn were only found between BL and Di (P<0.05, Fig. S1). No significant differences were detected for Cr or Co among all these three tidal flats (P>0.05). The average concentration of As was 2.84 mg/kg at BL, representing the highest among the three areas. Metal concentrations seemed higher in the summer than in the winter, but only As concentrations were significantly different between the two seasons (P<0.05, Fig. S1). In addition, there was no significant effect of sediment
layer on heavy metal concentrations (Fig. S1).

Among the eight heavy metals determined, six metals (Co, Cr, Cu, Ni, Pb and Zn) were collinear ($\rho>0.64$, $P<0.05$). In contrast, As and Cd did not follow the pattern of other metals, as significant correlations were only observed between As and temperature ($\rho=0.74$, $P<0.01$), NH$_4$-N ($\rho=0.61$, $P<0.05$) and C/N ($\rho=0.66$, $P<0.05$), and between Cd and nitrite ($\rho=-0.73$, $P<0.01$) and pH ($\rho=-0.76$, $P<0.01$).

### 3.2 Abundances and Ratios of N-cycling Gene Markers

Comparison of gene abundances is shown in Fig. 2 (for raw data of copy numbers are Table S1). The copy numbers of anammox bacterial 16S rRNA and N-cycling functional genes were determined for the 36 sediment samples. AOA-amoA genes varied between $1.0 \times 10^3$ and $3.3 \times 10^5$ copies g$^{-1}$ sediment (Fig. 2A–C; Table S1), which was between 0.5 to 26.6 times the level of AOB-amoA found in the samples (Table 2). Compared with AOB-amoA, AOA-amoA appeared to be more abundant across all the samples ($P<0.05$, $n=36$) (Fig. 2A–C). Among the denitrifying genes, nirK appeared to be the most abundant, with copy numbers ranging from $2.7 \times 10^3$ to $1.6 \times 10^7$ g$^{-1}$ sediment (Fig. 2D–F). The mean abundance of nirS was about half of nirK but 1.0 to 217.7 fold as much as that of nosZ genes (Table 2). The ratio between nitrite and nitrous oxide reductases (nirK+nirS)/nosZ varied greatly from 1.3 to 473.0. The abundance of AMB 16S rRNA gene ranged from $2.2 \times 10^3$ to $1.3 \times 10^3$ copies g$^{-1}$ sediment (Fig. 2A–C), with a mean value approaching to that of nosZ genes, whereas their ratios varied greatly from 0.1 to 11.6 (Table 2).

### 3.3 Correlation Analysis

In order to explore the relationship between gene abundances and environmental variables, Spearman’s correlations were performed (Table 3). Because the six heavy metals (Co, Cr, Cu, Ni, Pb, and Zn) were collinear, only Cu was considered as a representative here. For all gene abundances examined, most were negatively correlated with temperature ($\rho=-0.75$ to $-0.91$, $P<0.01$), except for AOA amoA and AMB 16S rRNA genes which showed no significant correlations ($P>0.05$). AOA also showed no correlation with other environmental variables, whereas AOB amoA was negatively correlated with the metal As ($\rho=-0.62$, $P<0.05$). Among the denitrifying genes and their combination examined, only nosZ was significantly correlated with Cd ($\rho=0.63$, $P<0.05$) and NO$_2$-N ($\rho=-0.74$, $P<0.01$). Notably, significant correlations between abundances of AMB 16S rRNA genes and Cu ($\rho=0.82$, $P<0.01$), nitrite, pH and salinity ($\rho=-0.64$ to $-0.79$, $P<0.05$) were observed (Table 3).

The correlations between ratios of gene copy numbers and environmental variables may give a clue to understanding the regulating mechanisms for genes of identical functions. The AOA/AOB amoA copy number ratios were significantly correlated with pH ($\rho=-0.52$, $P<0.05$) and the metals Cd ($\rho=0.62$, $P<0.05$) and Cu ($\rho=0.58$, $P<0.05$). The nirK/nirS ratios showed positive correlation with Cd ($\rho=0.87$, $P<0.01$), and negative with NO$_2$-N ($\rho=-0.85$, $P<0.01$), NO$_3$-N ($\rho=-0.58$, $P<0.05$) as well as pH ($\rho=-0.71$, $P<0.01$). However, correlations between other denitrifying gene ratios (i.e. nirS/nosZ, nirK/nosZ and
(nirS+nirK)/nosZ) and variables examined were not supported. AMB/nosZ, a potential indicator for the relative contribution of anammox and denitrification processes to N₂ production, was correlated with C/N (\( \rho = 0.78, P < 0.01 \)), temperature (\( \rho = 0.70, P < 0.05 \)), dissolved oxygen (\( \rho = -0.68, P < 0.05 \)) and NH₄-N (\( \rho = 0.59, P < 0.05 \)). In addition, a positive correlation was identified between AMB/nosZ and As (\( \rho = 0.61, P < 0.05 \)) (Table 3).

Correlations between different genes in samples cross locations and seasons were analyzed (Table 4). When all 36 sediment samples from both the upper and lower layers were considered, there was no correlation between AOA and AOB amoA genes; whereas nirS and nirK abundances were significantly correlated (\( \rho = 0.93, P < 0.01 \)). Interestingly, all the three denitrifying genes were positively correlated with AOB amoA gene (\( \rho = 0.42-0.63, P < 0.05 \)), whereas only nirS and AMB 16S rRNA genes were positively correlated with AOA amoA (\( \rho = 0.38, P < 0.05 \)). No correlation was observed between AMB and AOB. A similar pattern of these correlations was identified when only the upper layer samples were analyzed. Nevertheless, significant correlations between nirK and AOA (\( \rho = 0.59, P < 0.05 \)) were only obtained from the dataset for the upper layers; correlations between AOA and nosZ or AMB were observed from the dataset for both layer samples, but not the upper layer samples (Table 4).

4 Discussion

4.1 Ammonia Oxidizers

In this study, both ammonia oxidizers had significantly higher abundance in winter than in summer (Fig. 2). This seasonal change may be explained by strongly negative correlation between AOB and temperature (Table 3). However, because no significant correlations were found between AOA and the environmental factors measured in this study, factors contributing to seasonal changes of AOA in LZB estuaries remain unclear. This contrasts with previous studies showing that both AOA and AOB abundance were negatively correlated with the salinity gradient ranging from 0.6 to 31 PSU in the San Francisco Bay estuary [19], and that the highest AOA and AOB abundance were recorded at 20 PSU when a similar salinity range was examined in the Plum Island Sound estuary [40]. This discrepancy may be due to the high salinity (36.3-50.3 PSU) for most of our samples. Nevertheless, the high salinity explains that both AOB and AOA amoA gene copy numbers determined in this study were about two to three order of magnitude lower than these reported for other estuaries [41-44].

AOA outnumbered AOB in a majority of our samples, which is consistent with previous studies which showed that AOA usually dominated in more saline environments [41, 45-47]. However, AOB dominated in samples from Di and JL with salinity around 50 PSU, suggesting that the salinity is not the only determining variable in the LZB estuaries, other variables such as nitrite, pH, and C/N ratio may also impact the abundances of ammonia oxidizers [19, 43, 48, 49]. Our further analysis indicated a negative correlation between AOA/AOB ratio and pH (Table 3), which is consistent with previous notion that AOA outnumbers AOB in soils with lower pH [50]. Furthermore, we found a negative correlation between As (0.84-3.91 mg/kg) and AOB abundance, and that the AOA/AOB ratio was also significantly positively correlated to
both Cd (0.03-0.08 mg/kg) and Cu (1.32-11.06 mg/kg) in the LZB estuarine sediments (Table 3), contrasting to the study in the San Francisco Bay estuary, where Ni and Pd showed strong correlations with abundance of AOA [19]. Nevertheless, our results suggest different responses of AOA and AOB to heavy metal contaminated sediments, with AOB seemingly being more sensitive to As contamination. A similar pattern has been observed in highly contaminated soils (As, 10000 mg/kg; Pb, 200 mg/kg; Cu, 1600-2400 mg/kg) [51, 52], where AOB was negatively affected whereas AOA seemed more tolerant.

4.2 Denitrifiers

Of the three types of denitrifiers examined, the nirK-type was more abundant than nirS-type and nosZ, especially in BL and JL, suggesting a dominant role of nirK-type denitrifiers in denitrification in the LZB estuaries. The lowest nirK-type abundances were recorded in summertime samples from Di where both the water salinity (50.3 psu) and pH (8.61) were the highest. The dominance of nirK-type and lowest abundance of the nosZ-type denitrifiers in LZB estuarine tidal flats are consistent with a study on sediment of a constructed wetland [10], but contrast with several reports that nirS-type dominated in estuarine sediments [21, 22, 53]. This is consistent with the idea that nirS- and nirK-type denitrifiers have different habitat preferences, as suggested by several studies [9, 54]. In sediments of the hypernutrified Colne estuary, the decrease of nirS gene abundance in the more marine sites might be related to nitrate and ammonia gradient [55], whereas nirS was highest in the more marine sites and nirK abundance was highest in riverine sites [22]. In this study, however, the higher ratio of nirK/nirS was shown to be related to lower pH and NOx-N. The effects of these environmental variables on dominance of the two denitrifier types are thus confounding at present.

Trace metal availability may affect denitrification through the metalloenzymes and toxicity to benthic denitrifiers [24], and more generally, negative relationships between metals and the activity or the abundance of denitrifiers are found. For example, nirK was negatively correlated with Ag and methyl-mercury in the San Francisco Bay estuary [22]; both the abundance of nosZ gene and the denitrification rates in sediment decreased by the amendment of Cu (up to 79 mg/kg of wet sediment) in the Douro River estuary [53, 56]; lowest Cu concentrations (0 - 0.277 mg/kg of dry sediment) could yield a drastic decrease in the abundance of nirK, nirS and nosZ genes in salt marsh sediments [57]. Nevertheless, a positive correlation between nirS and Pb was also observed [22]. In this study, we found a significantly positive correlation between Cd (0.03 - 0.08 mg/kg) and nosZ and the ratio of nirK/nirS in these three tidal flats (Table 3). Such previous data along with ours, thus suggest that heavy metals, even presenting at relatively low levels, may be important factors influencing specific denitrifying populations or their relative abundance in estuarine sediments.

The high abundance of nirS and nirK genes compared with nosZ gene is an indicator of the genetic capacity of the system to potentially accumulate the N2O intermediary [10]. Therefore, the value of nirS+nirK-nosZ or the ratio of (nirS+nirK)/nosZ could be used as predictors of the potential for N2O emission. The seasonal effect on nirS+nirK-nosZ was significant (t-test, P<0.01; Fig. 2D), predicting a greater N2O emission potential in winter than in summer in the LZB estuarine tidal flats. This seasonal
pattern of N₂O emission has long been observed [58], although the N₂O flux rate was not determined in this study. Nevertheless, no significant correlations were found between metals and nirS+nirK-nosZ or (nirS+nirK)/nosZ in our study, contrasting to a previous investigation showing that N₂O production was stimulated with the progressive increase of metals (Cu, Zn, Cr and Cd) to estuarine sediments [53]. Relatively lower concentrations of heavy metals in the LZB estuarine tidal flats might explain this discrepancy.

4.3 Anammox bacteria

We found that AMB abundances were negatively correlated with salinity, pH and nitrite, and positively with Cu in the LZB estuarine sediments. This result is basically consistent with several previous studies which have showed that salinity [17], and nitrite concentration are significantly correlated with abundance of anammox bacteria [59]. Both high salinity and nitrite toxicity can inhibit anammox bacteria, which is understandable as the higher salinity challenges microorganisms with higher osmotic pressure, and nitrite suppresses the anammox process at certain threshold concentrations [60]. The inhibition on physiology of AMB may eventually lead to population decreases due to grazing pressure in the benthic microbial food webs. As for the positive correlation between Cu and AMB abundance found in this study, we are unable to give a proper explanation, since few studies have been carried out on effect of heavy metals on AMB [60]. Nevertheless, it is noteworthy that a previous study on closed marine systems has demonstrated that the addition of trace metals (Fe, Mn, Cu, Zn and Mo) enhances the denitrification processes [61], which could supply more NO₂⁻ as substrate for anammox.

To our knowledge, this study for the first time investigated the abundance ratio between a marker gene of AMB (i.e. specific 16S rRNA gene) and a nitrous oxide reductase gene (i.e. nosZ) in sediment samples, as a potential indicator of the relative contribution of anammox to N₂ production (%R₄amx). The rationale is that both the AMB and the nosZ-type denitrifiers are responsible for N₂ production, the abundance of these marker genes may be proxy of the capability of their functions. Although the relative contributions of these two processes were not investigated using ¹⁵N stable isotope labeling in this study, the variations of AMB/nosZ in relation to environmental factors might give a clue to further studies. Our correlation analysis showed that the ratio of AMB/nosZ was significantly and positively correlated with C/N ratio, temperature, concentrations of As and NH₄⁻N in sediments, and negatively with dissolved oxygen in the overlying water (Table 3). In agreement, the %R₄amx was positively correlated with both the organic carbon content of the sediment and the concentration of NO₃⁻ in the overlying water from intertidal flats in southeast England [62]. In the Chesapeake Bay, the %R₄amx ranged from 0 to 22%, with the highest rate in the freshwater portion of the main stem of upper Chesapeake Bay, where water column NO₃⁻ concentrations are consistently high [63]. Nevertheless, it has also been shown that higher bottom water oxygen concentrations inhibited dissimilatory nitrate reduction to ammonium (DNRA) and denitrification but stimulated both anammox activity and the %R₄amx [17]. Therefore, the usefulness of the abundance ratio of AMB 16S rRNA/nosZ as an indicator of AMB’s contribution to N₂ production is partly supported by these previous observations. Further studies are needed to reveal the relationships between this or alternative indicators (e.g. the ratio of anammox functional
gene to nosZ copy numbers) and %R_{anx}, which could benefit to large-scale investigations and our understanding on the spatiotemporal variations on the contribution of anammox to N₂ production in coastal ecosystems.

In summary, we have examined the spatiotemporal pattern of the abundance of N-cycling microbes in sediments of three hypernutrified LZB tidal flats where the heavy metal contamination were at relatively low levels. Overall, function-similar groups have showed niche specialization in the LZB estuarine sediments. AOA are more abundant than AOB in most cases, and their relative abundance is correlated significantly with the concentration of heavy metals (e.g. Cd and Cu) and pH. For denitrifiers, nirK-type usually outnumbers nirS-type, and nosZ-type is the lowest. The variations in abundances of nirS and nirK show a similar pattern by correlating with temperature, whereas their copy number ratio is correlated with pH, nitrite, nitrate, and cadmium. The variation of the ratio of nirK and nirS abundance depends on nitrogen load and cadmium. Abundance of nosZ-type is correlated with not only temperature, but also nitrite and Cd in sediments. Anammox bacterial abundances are strongly correlated with salinity, pH, nitrite and Cu. Furthermore, we have explored for the first time the associations between environmental factors and combinations or ratios of copy numbers of nitrogen cycling genes. For example, the abundance ratio of anammox bacterial 16S rRNA gene to denitrifying nosZ gene, which could be a potential indicator for the contribution of anammox to N₂ production, is correlated to temperature, dissolved oxygen in overlying water, and ratio carbon to nitrogen and concentrations of ammonium and As in sediments. For the two indicators of genetic potentials for N₂O emission, (nirS+nirK-nosZ) and (nirS+nirK)/nosZ, the former is only correlated to the temperature, whereas the latter shows no correlations with any variables determined. Taken together, our study stresses that abundances of N-cycling functional groups respond differently to variations of environmental conditions, and multiple factors including heavy metals with relatively low concentrations may play a role in shaping nitrogen cycling processes in these estuarine tidal flats.

Acknowledgments
This work was supported by the CAS Knowledge Innovation Project (No. KZCX2-YW-JC203), the Natural Science Foundation of China (No. 41206155), the CAS Scientific Innovation Program - Interdisciplinary Field, the One Hundred Talents Program of CAS, and International Partnership Program for Creative Research Teams. Thanks are due to Ms. Xiaohong Guo, Beibei Xing and Drs. Kexin Zhao and Xiaobo Liu for helps in sampling and laboratory assistance.

Conflict of Interest
The authors have declared no conflict of interest.
