Five poTAGEs and a COLT for an unrealistic predictor

Pierre Michaud
Inria

1 Summary

The predictor we submit to the competition is for exploring the limits of branch prediction, it is not intended to be implemented in hardware. The proposed predictor consists of 5 huge TAGE predictors which we have tuned for better accuracy under huge storage budget. The overall prediction is obtained by combining the 5 TAGE predictions via COLT fusion. One of the 5 TAGE components takes a conventional global path as input. The 4 other TAGE components take as input different sorts of first-level histories. On the CBP-4 traces, the proposed predictor achieves 1.782 MPKI.

2 The TAGE predictor

The predictor we submit to the unlimited-size track is based on a modified version of the TAGE predictor [12, 11]. A TAGE predictor consists of several tagged tables and one tagless table. Each entry of the tagless table contains a taken/not-taken counter. Each entry of a tagged table contains a tag, a taken/not-taken counter, and a $u$ bit. The tagless table is indexed with the address of (conditional) branches: it provides a default prediction when none of the tagged table give a hit. The tagged tables are indexed through a hash on the branch address and the global path [8]. The path lengths follow a geometric progression [10]. TAGE is based on the PPM principle [1]. In a PPM-like predictor [6], the prediction is always given by the longest hitting path. However, there are some situations where the second longest hitting path is likely to be more accurate than the longest one, especially when the longest hitting path entry is “fresh”, i.e., it has just been initialized but not yet updated. TAGE exploits this fact with a single USE_ALT_ON_NA counter (acting like a meta-predictor [5]) for selecting between a fresh longest hitting prediction and the second longest hitting prediction [12]. The $u$ bit in each entry indicates if that entry is likely to be useful or not. When the $u$ bit is set, it protects the entry from being “stolen” [6]. All the $u$ bits are cleared when it is detected that the predictor is “jammed” [11]. The $u$ bit is also used to detect if an entry is fresh: an entry is considered fresh if the $u$ bit is not set and the taken/not-taken counter value is weak [12].

3 The poTAGE predictor

3.1 Post predictor

The poTAGE predictor, shown in Figure 1, is similar to TAGE, except that we replace the USE_ALT_ON_NA mechanism with a post-predictor (poTAGE = post-predicted TAGE). In the submitted predictor, the taken/not-taken counter in each TAGE entry is 3-bit wide. Our post-predictor is a 1024-entry table, each table entry holding a 5-bit taken/not-taken counter. The post-predictor is indexed with the $u$ bit and counter value of the longest hitting TAGE entry, and the counter values of the second and third longest hitting TAGE entries (10 index bits total). The 5-bit counter is used and updated like a conventional taken/not-taken counter [13].
3.2 Ramp-up

In a TAGE predictor, the update is crucial, it must be done very carefully: only the longest hitting counter is updated [6], and only a few new entries are allocated upon a misprediction for path lengths greater than the longest hitting length [12, 11]. However, because we assume a huge predictor size, it is possible to use a more aggressive update policy to decrease mispredictions due to cold-start effects:

Instead of updating only the longest hitting counter, we update all the hitting counters, whether or not the branch was correctly predicted.

Instead of allocating a few new entries, and only upon a misprediction, we allocate entries for all the path lengths greater than the longest hitting length, whether or not the branch was correctly predicted, and provided the entries can be stolen (u bit not set). We stop doing aggressive allocation for path lengths greater than 200 branches when all the hitting counters are saturated.

We use this aggressive update policy during what we call the ramp-up period. When the ramp-up period is over, we switch to the careful update policy implemented in the ISL-TAGE predictor [11].

The ramp-up period length is roughly proportional to the predictor size. For the submitted predictor, we set the ramp-up period to one million mispredictions\(^1\). A ramp-up period might also be useful in (large) real branch predictors. However the problem in a real predictor is how to detect when to start the ramp-up.

4 Beyond TAGE

So far, the most accurate branch predictors, including TAGE, belong to the family of two-level branch predictors [14, 9, 15]. Yeh and Patt provided a taxonomy of two-level branch predictors [16]. In particular, they distinguished predictors according to their first history level.

The 2006 and 2011 TAGE predictors [12, 11] are “global” schemes, as their first-level history consists of a single global path shared by all the branches.

Global schemes are the most accurate two-level predictors that we know. However they have some limits. The footprint of a static branch in a particular TAGE table grows exponentially with the path length used for that table. The footprint also grows very quickly with branch entropy: the more unpredictable the branches, the larger the footprint [7]. A large footprint incurs cold-start and capacity misses in a TAGE predictor. Applications exhibiting randomness in their control flow behavior are difficult to predict by a global scheme such as TAGE not only because of their intrinsic randomness, but also because of the large footprint.

Per-address schemes, i.e., predictors that use per-branch first-level histories [16], suffer less from this problem. Indeed, a global path contains some “noise”, i.e., some entropy that does not bring any correlation information but just grows the footprint [2]. In an ideal (i.e., large enough) per-address scheme, each static branch is predicted with its own subpath, which it does not share with other static branches. Unlike global schemes, per-address schemes cannot exploit global branch correlations, only local correlations. However, in a per-address scheme, hard-to-predict branches do not “pollute” the subpath of easy-to-predict branches.

Global and per-address schemes are two extreme points in the set of all possible two-level predictors. Yeh and Patt also introduced per-set schemes in their taxonomy[16]. Per-set schemes have been largely ignored since their introduction, until recently when Ishii et al. introduced two per-set schemes in their FTL++ predictor [3].

In a per-set scheme, there are several subpaths like in a per-address scheme, but a subpath is shared by several static branches. Subpath sharing generally exists in practical implementations of per-address schemes because of the limited storage for first-level histories. However, in a per-set scheme, subpath sharing is intentional: the goal is to exploit both local and (to some extent) global correlations, but with a smaller footprint than global schemes.

In a global scheme such as TAGE, hash functions are applied to the global path for indexing the tagged tables. Path aliasing can occur if two different global paths map to the same table entry and tag. In a global scheme, we generally try to minimize path aliasing by using “good” hashing functions. Using a per-set scheme can be seen as intentionally introducing path aliasing for decreasing the footprint. Blind path aliasing is likely to degrade the predictor’s ability to exploit global correlation. Still, the hope is that the benefit of a smaller footprint outweighs this degradation. This is generally not true for all branches but for a few of them. This is why per-set schemes should not be used alone but as components of a hybrid predictor, as Ishii et al. did in the FTL++ predictor. The type of path aliasing that per-set schemes exploit is based on the assumption that branches which are statically close to each other are more likely to be correlated than distant branches. Other forms of intentional path aliasing can be imagined (cf. Section 6).
Table 1: The 5 poTAGEs. The poTAGE tables are very large. P0 is roughly twice larger than each of the other predictors. The COLT table (not listed) is also very large.

Figure 2: The multi-poTAGE predictor.

5 The multi-poTAGE predictor

The proposed predictor, called multi-poTAGE, is depicted in Figure 2. It is a hybrid predictor [5] combining 5 different poTAGE predictors P0, P1, P2, P3 and P4. P0 is the global path poTAGE described in Section 3. The other predictors do not use a global path:

- P1 uses 32 per-address subpaths
- P2 uses 16 per-set subpaths with 128-byte sets
- P3 uses 4 per-set subpaths with 2-byte sets
- P4 uses 8 frequency-based subpaths

Predictor P4 uses a new sort of first-level history: frequency-based subpaths. P4 does not belong to the taxonomy of Yeh and Patt but to a more general class of two-level predictors.

In a two-level predictor, the first-level history consists of a set of subpaths that we call a path spectrum. At prediction time, a subpath \( S_p \) is selected from the path spectrum. Subpath \( S_p \) is used to access the second-level history (here, poTAGE), yielding a prediction. At update time, the branch updates one of the subpath \( S_u \). In the proposed multi-poTAGE, \( S_p \) and \( S_u \) are always the same.

The spectrum of P0 consists of a single subpath shared by all the branches, i.e., it is the whole global path. The spectrum of P1 consists of 32 subpaths, and \( S_p(=S_u) \) is selected with the 5 least significant branch address bits 0 to 4 (per-address first level). The spectrum of P2 consists of 16 subpaths, and \( S_p(=S_u) \) is selected with branch address bits 7 to 10 (per-set first level).

The spectrum of P4 consists of 8 subpaths. The subpath \( S_p(=S_u) \) is selected as follows. The branch address is used to index a Branch Frequency Table (BFT). If the BFT is large enough, each static branch uses a distinct BFT entry. Each BFT entry holds a counter indicating the current frequency of the static branch. The frequency of a branch is the number of times the branch has been executed until now since the counter was reset\(^2\).

Predictor P4 seeks to exploit correlations between branches having (roughly) the same frequency. Each of the 8 subpaths \( S[0] \) to \( S[7] \) corresponds to a distinct frequency bin. Let \( F_{\text{max}} \) be the maximum branch frequency so far. Branches whose frequency lies in \( [F_{\text{max}}/2, F_{\text{max}}] \) are predicted with subpath \( S[0] \). Branches whose frequency lies in \( [F_{\text{max}}/4, F_{\text{max}}/2] \) use subpath \( S[1] \). Branches whose frequency lies in \( [F_{\text{max}}/8, F_{\text{max}}/4] \) use subpath \( S[2] \). And so forth.

Note that, after an initial period, the dynamic instances of a static branch will generally use the same subpath.

\(^2\)In the submitted branch prediction algorithm, we reset the frequency counters only once, when the simulation starts.
7 Experimental analysis

P0 is the most accurate of the 5 poTAGEs as a single component. Compared with the USE_ALT_ON_NA mechanism used in previous TAGE predictors, the post-predictor decreases the number of mispredictions by 5% on the CBP-4 traces. Using a ramp-up period yields a further 4% decrease. To evaluate the importance of each of the 5 poTAGEs in the multi-poTAGE predictor, we selectively disabled some of them. P2 is the second most important predictor after P0, followed by P1, P4 and P3 in that order. Adding P2, P1, P4, and P3 (successively and in that order) to P0 decreases the number of mispredictions by respectively 5%, 3%, 2.5% and 1%. In total, the multi-poTAGE predictor has 10% fewer mispredictions than P0 alone.

8 Conclusion

The prediction accuracy of TAGE is very high. Still, when considering a huge storage budget for limit studies, a more aggressive update policy can be used. Global path predictors such as TAGE are theoretically able to capture all the branch correlations if the global path is long enough. However, a global path suffers from “noise” from branches that bring no correlation information but grow the footprint. To (try to) solve this issue, we combined five poTAGEs with different first-level histories, using COLT fusion. This brute force approach may not be reasonable for a realistic predictor. Future research should try to look for more cost-effective solutions.
