Keywords: TiO₂(B), Fe-TiO₂(B), microwave synthesis, Li-ion batteries, scale-up

Abstract

We present here a novel simple method for the synthesis of highly pure $\text{TiO}_2(\text{B})$. The fast microwave-assisted synthetic route allows facile scale-up of the process. Aiming at an application of the titania polymorph as negative electrode for Li-ion batteries, we have prepared a Fe-containing $\text{TiO}_2(\text{B})$ and tested the electrochemical performances of both pure and Fe-containing materials. Fe insertion in $\text{TiO}_2(\text{B})$ allows enhancing capacity and rate capability.

1. Introduction

Making technologies such as electric vehicles or grid storage viable calls for efficient energy storage devices. Among these, Li-ion batteries, developed in the 90's, have been a revolution for the portable electronic devices field: their energy density is superior to that of conventional batteries by a factor 2 to 3 [1–3]. The Li-ion technology nowadays represents a \$11.7 billion market, and is still growing [2]. Despite this commercial success and high energy density, the current device generation has relatively poor power output properties compared to other energy storage systems such as supercapacitors, which on the other hand present very small energy densities [4]. For high-power applications, a compromise between high energy density and power output might be interesting. This is where materials with pseudocapacitive behavior [5–7], such as titanium dioxide $\text{TiO}_2(\text{B})$, find an interest.

Among potential candidates to replace the commonly used carbon graphite as anode material, also titanium-based materials, such as titanate spinel $\text{Li}_4\text{Ti}_5\text{O}_{12}$ or the different polymorphs of titanium dioxide, have been investigated [8–12]. Among the latter, $\text{TiO}_2(\text{B})$ appears as very promising. Indeed, it exhibits low toxicity, is cost effective and has very good rate capability and safety (because of its higher lithiation potential, 1.6 V vs. Li/Li^+ , compared to that of graphite, 0.1 V vs. Li/Li^+) [13]. When compared to other polymorph, titania bronze exhibits the highest capacity (335 mAh/g, compared to 170 mAh/g for brookite, 250 mAh/g for rutile and 285 mAh/g for anatase) [13]

Though, the main interest of $\text{TiO}_2(\text{B})$ lies in its pseudocapacitive behavior towards insertion of lithium ion [13–16]. Recent studies make the surface structure responsible for this substantial Li^+ uptake. For high specific area materials with strained morphology (such as nanotubes or nanowires), surface sites are quickly filled during the first part of discharge,

followed by the insertion of the absorbed ions into the interior of the material through radial pathways connecting the different insertion sites [17]. However, the origin of this enhanced high power cycling is still subject to debate. First synthesized in 1980 by Marchand *et al.* [18] with solid chemistry methods, $\text{TiO}_2(\text{B})$ is a metastable phase that transforms into anatase above 550°C at atmospheric pressure. The first synthesis of nanostructured $\text{TiO}_2(\text{B})$ has been reported by Kasuga and co-workers in 1999 [19]. The classical approach is hydrothermal synthesis in strong alkaline conditions using variety of different starting materials (TiO_2 [12], TiCl_4 [9], Tetrabutyl titanate [20]). Under such severe conditions, the isomorphous alkali titanate precipitates. Subsequent ion exchange and calcination at relatively low temperatures are used to remove the alkali ions and to obtain the bronze polymorph. Preparation of $\text{TiO}_2(\text{B})$ by this route raises several problems: first, its metastability impedes high pressures or temperatures during synthesis or calcination. Therefore, even if the synthesis is performed at low temperature, anatase impurities cannot be avoided in the final product [21]. The presence of such impurities is difficult to detect through simple X-ray Diffraction (XRD) analysis but are efficiently revealed by Raman spectroscopy and galvanostatic cycling (anatase shows a characteristic plateau at 1.8 V). Secondly, long hydrothermal syntheses are not viable for many applications (reducing synthesis time reduces the yield). Therefore, microwave-assisted synthetic methods are an interesting alternative as they have proven to be energy efficient, cost effective and quicker than classical hydrothermal methods for the production of anatase [22].

Inorganic materials often have enhanced performance when containing aliovalent cations. Notably, for other TiO_2 polymorphs, cation insertion has proven to be an efficient technique to increase their low intrinsic conductivity [23]. When it comes to $\text{TiO}_2(\text{B})$, cation insertion has already been performed and its effect on magnetic and photocatalytic properties

studied. Only very recently it has been shown that Nb-insertion has positive effect on tap density and microstructure of $\text{TiO}_2(\text{B})$, leading to higher Li storage capacity [24].

In this study, we report a novel soft chemistry synthesis of phase-pure $\text{TiO}_2(\text{B})$ by hydrothermal synthesis and microwave-assisted synthesis, which allowed us to reduce the reaction time by over 95%. We also demonstrate the potential of the incorporation of third-party element (here iron) in titania bronze to improve its electrochemical cycling properties. We have chosen iron in order to improve the electrical conductivity of the final material. Notably, the high atomic percentage of iron used (ca. 10%) makes this incorporation difficult to describe as actual doping. The insertion method was also successfully extended to other cations such as Cu^{2+} , Mn^{2+} , Nb^{5+} , W^{6+} , which were not discussed here.

Crystallinity and phase composition of the synthesized materials were characterized by XRD, and the phase purity was confirmed by Raman spectroscopy. Size and morphology of the nanoparticles were analyzed through Transmission Electronic Microscopy (TEM). The efficiency of the Fe-insertion procedure was analyzed by ^{57}Fe Mössbauer spectroscopy. Li-ion intercalation properties were tested by galvanostatic cycling at different cycling rates.

2. Experimental

2.1. Synthesis

Phase-pure $\text{TiO}_2(\text{B})$

Hydrothermal synthesis

1.0 g of titania (PC500) was mixed with 75 mL of an aqueous solution of KOH (15 mol.L^{-1}) under constant stirring. The resulting white suspension was kept under vigorous

stirring for 30 min before alternating stirring and dispersion in an ultrasonic bath (5 min each) during 30 min. The resulting white solution was transferred to Teflon-lined autoclaves and kept at 150 °C for 72 h. The resulting white product was washed with deionized water until the pH of the supernatant was lower than 12. Then, the filtered solid was stirred with an aqueous solution of HCl (0.1 mol.L⁻¹) for 4 h to exchange the intercalated K⁺ for protons. Subsequently, the solid was washed again with deionized water until the pH of the supernatant was higher than 5 and then dried at 70 °C for 15 h to produce hydrogen titanate. The resulting white solid was finally annealed at 400 °C for 3 h to obtain pure titania. The procedure was successfully scaled-up by a factor of 3. The typical yield is above 95 % (950 mg).

Microwave-assisted synthesis

Phase-pure titania bronze was also obtained using microwave-assisted heating. The experimental procedure was similar to hydrothermal conditions except for heating step. The suspension of titania in 15 mol.L⁻¹ KOH was transferred to Teflon microwave tubes and kept at 150 °C for 3 h. The following steps were identical to those of hydrothermal synthesis. The procedure could also be successfully scaled-up by a factor of 3.

Fe-containing TiO₂(B)

During the initial synthesis step, 0.506 g of Fe(NO₃)₃·9H₂O (corresponding to a Fe/Ti atomic ratio of 0.1) was added to the dispersion of titania in 15 mol.L⁻¹ KOH under constant stirring. Alternative stirring and ultrasonic dispersion were carried out again (5 min each, for a

total of 30 min). For hydrothermal synthesis and microwave-assisted synthesis the following synthetic steps were identical to those used for synthesizing pure $\text{TiO}_2(\text{B})$.

These experimental procedures are summarized in the flowchart in Figure 1.

Figure 1. Flowchart of the synthetic methods to obtain pure and Fe-containing $\text{TiO}_2(\text{B})$

2.2. Electrochemical tests

The titania powder was sieved using a 50 μm mesh sieve, and intimately mixed with carbon black (Y50A) and PolyViniliDene Fluoride (PVdF) in a weight ratio of 77 : 8 : 15, respectively. The homogeneous slurry obtained by addition of N-methyl-2pyrrolidone (NMP) was tape casted on a roughened copper foil (provided by Schlenk Metalfolien, for enhanced adhesion) using a doctor blade system, to obtain 20 μm thick films. The punched-out disks were used as the working electrodes.

The working electrodes were assembled in SwagelokTM cells. Metallic lithium was used as reference and counter electrode. Whatman glass-fiber was used as the separator and impregnated with the electrolyte, a solution of 1 M LiPF_6 in a mixture of ethylene carbonate, propylene carbonate and dimethyl carbonate in a weight ratio 1 : 1 : 3. Since both metallic lithium and the electrolyte are sensitive to air and moisture, the device was assembled in a glove-box under argon atmosphere.

As-built devices were tested in galvanostatic mode at different cycling rates, from C/10 to 5C, where C/n corresponds to a current for which one mole of lithium ion is inserted per mole of TiO_2 in n hours.

2.3. Characterization

A Synthos 3000 microwave oven (Anton France) was used for heating the suspensions under microwave irradiation. Powder XRD analyses were performed with a Bruker D8 X-ray diffractometer operating in the Bragg-Brentano reflection mode equipped with a nickel filter to select the Cu-K_α radiation. The data were collected in the $2\theta = 10^\circ - 70^\circ$ range with 0.05° steps. Pattern analyses were performed using the ICDD DD View PDF-4+ 2009 RDB base, (JCPDS 00-021-1272, 00-021-1276 and 00-46-1238 for anatase, rutile and $\text{TiO}_2(\text{B})$, respectively).

The morphology and the average particle size of the samples were analyzed by TEM using a Tecnai spirit G2 apparatus equipped with a Gatan CCD camera and operating at 120 kV (LaB_6). Carbon-coated copper grids were used as sample holders. High resolution TEM (HRTEM) and STEM EDX mapping were performed at 200 kV using a Jeol 2100F apparatus (LaB_6).

Raman spectra were recorded using a LabRam ARAMIS IR² (Horiba Jobin Yvon) spectrometer with a helium neon laser working at 633 nm.

Specific surface areas were measured by N_2 physisorption at 77 K using a Belsorb Max instrument. The Brunauer-Emmett-Teller (BET) method was applied to calculate the specific surface area. Electrochemical cycling was carried out in galvanostatic mode on a Biologic multichannel potentiostat.

⁵⁷

Fe transmission Mössbauer spectroscopy data were recorded in the constant acceleration mode with a $^{57}\text{Co}:\text{Rh}$ source. During the measurements, the source was always

kept at room temperature whereas the temperature of the sample was varied between 4.5 K and room temperature using a Helium gas-flow cryostat. The velocity scale was calibrated with the magnetically split sextet spectrum of a high-purity α -Fe foil as the reference absorber. The spectra of Fe-containing $\text{TiO}_2(\text{B})$ were fitted to appropriate combination of Lorentzian profiles by least-squares methods using the computer program Isofit [25]. In this way, spectral parameters such as quadrupole splitting (Δ), isomer shift (δ), linewidth (Γ) and relative resonance areas of the different spectral components were determined. The isomer shifts are given relative to α -Fe metal.

3. Results and discussion

3.1. Synthesis

Hydrothermal synthesis

The synthetic method used allows facile and efficient synthesis of phase-pure $\text{TiO}_2(\text{B})$ with high yields. This method is a modification of that developed by Kasuga and co-workers [19]. The main modification lies in the nature of the alkaline solution used (15 mol.L⁻¹ KOH in our case). We tested different solid precursors (Cristal PC500 TiO_2 , Evonik P25 TiO_2 or lab synthesized anatase [22] and rutile [11]). We noticed that when the precursors contain rutile, insufficient alkaline treatment leads to rutile impurities in the final product. The suspension is then submitted to thermal treatment in autoclaves under self-generated pressure conditions (180 °C for 3 days). Reduction of the reaction time simply leads to lower synthetic yields (for this method, yield is over 95 %). The alkaline titanate obtained in this step is then subjected to ionic exchange to exchange the alkaline ions in the interlayer space for protons. This step can be performed with several methods, using HCl or HNO_3 , in a concentration

range from 0.1 to 1 mol.L⁻¹, for 4 to 24 hours. In our case, this exchange is performed by dispersion of the alkaline titanate in HCl (0.1 mol.L⁻¹) for 4 h. A final calcination step leads to dehydration and condensation of the layered titanate acid to obtain TiO₂(B).

Figure 2. XRD patterns for pure and Fe-containing TiO₂(B), synthesized under hydrothermal conditions (a) and for microwave-assisted syntheses (b). All patterns are plotted vs. the reference for TiO₂(B), black sticks.

The XRD of the final product is in good agreement with reference patterns for TiO₂(B) (JCPDS # 00-46-1238 for TiO₂(B)) (Figure 2). However the low crystallinity observed by XRD demands further characterization to confirm the purity of the synthesized phase. As previously reported [26], anatase-to-TiO₂(B) ratio in mixed phases can be easily determined using Raman spectroscopy, even at low crystallization level.

Figure 3. Raman spectra of pure and Fe-containing TiO₂(B), synthesized under hydrothermal conditions (a) and for microwave-assisted synthesis (b)

High purity of the obtained phase was confirmed by this technique, as no peak corresponding to anatase can be seen on the spectrum (Figure 3, main peaks positions for anatase (144, 398, 518, and 639 cm⁻¹). However, whether the high yield in TiO₂(B) phase, meaning higher phase stability, is due to the reduced hardness of K⁺ vs. Na⁺ and/or to the increased size of K⁺ imposing steric constraints favoring the formation of the layered titanate phase cannot be answered with certainty at this point.

The morphology of the particles and their size distribution was analyzed by transmission electronic microscopy (TEM). Nanoparticles are single crystals (Figure 4) and,

in agreement with previous studies [12,27], they have a nanorod morphology, probably formed from rolled nanosheets, which width is in the 5-9 nm range and length up to 100 nm. Analysis of micrographs shows lattice fringes with distances of 6.24 Å, corresponding to the [001] interlayer spacing along the nanorods of $\text{TiO}_2(\text{B})$. That is possibly consistent with previous studies that report morphology retention along the synthetic path (from alkaline titanate to titania bronze)[28] and the c axis perpendicular to the rods, at least until the titanate acid intermediate [29]. These results are confirmed by electron diffraction (not shown), which does not show any signal typical of anatase or of other titania polymorphs in the diffraction patterns. This result confirms the high phase purity of the final product.

Microwave synthesis

As highlighted by previous studies, formation of metastable $\text{TiO}_2(\text{B})$ is strongly dependent on synthesis parameters such as the reaction time, making the synthesis of $\text{TiO}_2(\text{B})$ with microwave-assisted processes by no means evident. The synthetic route previously described was tested with an alternate heating mode, under microwave irradiation. $\text{TiO}_2(\text{B})$ was successfully obtained in this way. At this point, the different characterization techniques used exhibit no significant differences between microwave-assisted and classic hydrothermal syntheses neither by XRD (Figure 2) nor by Raman spectroscopy (Figure 3). As an example, Figure 4 shows TEM images of the particles obtained under hydrothermal conditions. Microwave synthesis allows subsequent reduction of the reaction time by about 95 %, increases cost-effectiveness (by reducing energy consumption) of the synthesis and allows an easier scale-up of the synthesis.

Figure 4. TEM micrographs for pure $\text{TiO}_2(\text{B})$ (a) and Fe-containing $\text{TiO}_2(\text{B})$ (b) synthesized under hydrothermal conditions.

Fe-containing TiO₂(B)

A Fe precursor was added to the initial dispersion of anatase in KOH to obtain Fe-containing TiO₂(B). The following synthetic steps were identical to those performed in the case of phase-pure TiO₂(B). This synthetic methodology was also successfully applied to Cu²⁺, Mn²⁺, Nb⁵⁺ or W⁶⁺ cations (not shown). We also successfully transposed the synthetic path for Fe-containing TiO₂(B) to microwave-assisted synthesis. The final powders have an ochre-like coloration, and the UV-Vis absorption spectra of the Fe-containing samples exhibit an additional peak around 485 nm (Figure 5) which is in line with Fe insertion in the TiO₂. According to XRD (Figure 2), samples obtained by both heating modes are very similar as for phase-pure titania bronze. XRD patterns do not exhibit new peaks, nor shift of TiO₂(B) peaks. This result rules out the presence of additional crystalline phases such as iron oxides, but not of additional Fe-containing amorphous phases.

Figure 5. UV/VIS spectra without Fe³⁺ (a) and (b) with Fe³⁺ synthesized under hydrothermal conditions

In order to gather more information on the chemical state of the iron in these samples, they were studied by ⁵⁷Fe Mössbauer spectroscopy both at room temperature and at 4.5 K. The spectra at both temperatures of the sample obtained by hydrothermal synthesis are shown in Figure 6. Both spectra show a single paramagnetic doublet with hyperfine parameters typical of trivalent iron in the octahedral coordination. The similarity of the two spectra, and the lack of magnetically split components at low temperature are in line with the absence of iron oxides in the samples. In fact, nanosized iron oxides usually show a superparamagnetic

behavior at room temperature, thus leading to a simple doublet in the Mössbauer spectrum which could be confused with that of Fe atoms incorporated in the TiO_2 lattice. At liquid helium temperature, however, even very small iron oxide nanoparticles are expected to be largely below the blocking temperature, giving rise to a magnetic hyperfine splitting, *i.e.*, to a hyperfine magnetic sextet, in the Mössbauer spectrum. The lack of magnetic ordering at low temperature observed in our case is thus in line with the absence of any kind of more or less crystalline iron oxide, and confirms that the iron atoms are most probably incorporated in the $\text{TiO}_2(\text{B})$ lattice.

Figure 6. Mössbauer ^{57}Fe spectra of Fe-containing $\text{TiO}_2(\text{B})$, synthesized under hydrothermal conditions, measured at 295 and 4.5 K.

TEM micrographs show the same characteristic distances as in pure $\text{TiO}_2(\text{B})$. The Raman spectrum (Figure 3) exhibits a peak intensity increase in the case of Fe-containing samples, especially in the $220\text{-}250\text{ cm}^{-1}$ area, which origin could not be attributed yet. No new band, however, could be identified in the Raman spectra of iron containing samples. Moreover TEM-EDX mapping analyses clearly showed a perfect homogeneous repartition of Fe in the TiO_2 sample (for HT and MW samples) which not only demonstrates the presence of iron in the final product, but also is in line with the homogeneous incorporation of iron in the lattice of $\text{TiO}_2(\text{B})$ (Figure 7).

Figure 7. STEM-EDX for Fe-containing $\text{TiO}_2(\text{B})$ synthesized under hydrothermal conditions, elemental maps for Ti, O and Fe.

In conclusion, Mössbauer spectroscopy, UV and SEM are in perfect agreement and show that, for the hydrothermal as well as for the microwave-assisted samples, a single Fe containing phase is present.

3.2. Electrochemistry

Both samples were tested at several cycling rates, from C/10 to 5C. For both samples (with or without iron), classic hydrothermal synthesis or microwave-assisted synthesis, were electrochemically tested in lithium batteries. For all samples, galvanostatic curves show no plateau at 1.8 V, which is characteristic of the anatase phase (Figure 6). This confirms the phase-purity of the synthesized samples and a monophasic insertion mechanism for $\text{TiO}_2(\text{B})$, without phase transformation throughout cycling [24,30]. Furthermore for all curves the first cycles are quite similar confirming the absence of iron oxide active phase vs Li.

The samples were cycled 5 or 10 cycles at subsequently increased cycling rate as presented in Figure 8. For all samples, the capacity decreases when the cycling rate increases. Note that the offset between charge and discharge at low cycling rates (C/10, Figure 8, or lower, not shown) which is attributed to parasite reactions of the electrolyte cannot be seen at higher cycling rate. This phenomenon is most likely linked to the electrolyte degradation processes slower than the Li^+ insertion in TiO_2 . Galvanostatic curves evidence a higher coulombic efficiency at increased cycling rates, which is consistent with the pseudocapacitive behavior of $\text{TiO}_2(\text{B})$ and with presence of secondary processes which are kinetically limited. Both significant irreversible capacity upon first discharge and systematic higher capacity on discharge than on charge in further cycling are observed for all samples. These phenomena are much more enhanced for HT samples than for MW samples whereas the surface area of the HT powder ($260 \text{ m}^2.\text{g}^{-1}$) is the same than the MW one ($267 \text{ m}^2.\text{g}^{-1}$). These findings are in

agreement with studies stating reduction potential of EC, DMC and PC in the range of 0.9-1.3 V [31,32].

These reactions might also be linked to the intrinsic nature of this material. On the one hand, TiO_2 features well-known catalytic properties, which can lead to destabilization of electrolytes, and on the other hand, the TiO_2 surface carries always chemi- and/or physisorbed H_2O and OH groups. Upon contact with lithium, they form irreversibly strong Ti-O-Li bonds accounting for the main part of the capacity loss upon first cycle, while the liberation of proton is likely to initiate electrolyte reduction [33].

The capacity is stable regardless of the applied cycling rates. The capacity observed for hydrothermal syntheses appears higher than that observed for microwave ones, 180 mAh/g to 130 mAh/g for HT, and 140 mAh/g to 100 mAh/g for MW for phase-pure $\text{TiO}_2(\text{B})$, 230 mAh/g to 170 mAh/g for HT and 170 mAh/g to 125 mAh/g for MW for iron-containing $\text{TiO}_2(\text{B})$, at C/10 to 5C cycling rate, which cannot be explained by a variation of the surface area of the powders which might enhance the surface of reaction with Li. Presumably the crystallinity of MW samples is lower than that of the HT samples, promoting the solubility of particles in the electrolyte and leading to lower columbic efficiency.

We evidence overall capacity increase up to 30 % for classic hydrothermal syntheses and 15% for microwave-assisted syntheses, for iron-containing samples.

Figure 8. Galvanostatic curves of pure $\text{TiO}_2(\text{B})$ (a) and (c); and Fe-containing $\text{TiO}_2(\text{B})$ (b) and (d) prepared by hydrothermal and microwave-assisted synthesis respectively.

3. Conclusion

We present here a simple a soft-chemistry synthesis of highly pure $\text{TiO}_2(\text{B})$, by hydrothermal and microwave-assisted synthesis, the latter being much faster and energy efficient and therefore attractive for up-scale. By using these simple methods we succeed in the preparation of highly pure Fe containing $\text{TiO}_2(\text{B})$ samples. The iron insertion in the $\text{TiO}_2(\text{B})$ has been demonstrated by microscopy (TEM and EDX analysis) and Mössbauer spectroscopy. $\text{TiO}_2(\text{B})$ HT and MW have been electrochemically tested vs Li. Former show higher capacity and rate capability than latter. This is attributed to a higher crystallinity for HT powder in comparison to MW one, which leads to ia better stability of the active material towards the electrolyte. Fe- $\text{TiO}_2(\text{B})$ samples, HT as well as MW, show higher performance than $\text{TiO}_2(\text{B})$ without Fe, likely due to an increase of the electronic conductivity, since neither structural crystallographic nor morphologic changes have been evidenced in Fe-samples. Indeed a 230 mAhg^{-1} capacity can be stabilized at low rate.

This work of doping of $\text{TiO}_2(\text{B})$ is pioneering and the preliminary electrochemical results show that this way is efficient to improve the electrochemical performance in term of energy density as well as of power. These results may pave the way for a low cost and environmentally benign electrode presenting good performance in lithium battery.

TiO₂+15 mol.L⁻¹ KOH
Stirring for 30 min
Stirring/Ultrasonic bath, 5 min each, for 30 min

72 h at 150°C in autoclaves

Removal of supernatant
Washing with DI water
until pH<12

HCl 0,1 mol.L⁻¹, 4 h
Washing with DI water
until pH>5

Drying, 70 °C - 15 h
Annealing, 400 °C – 4 h

Facile synthetic route towards nanostructured Fe-TiO₂(B), used as negative electrode for Li-ion batteries

Remi Grosjean^{1,2,3,4}, Marcus Fehse¹, Stéphanie Pigeot-Remy^{2,3,4}, Lorenzo Stievano^{1,5}, Laure Monconduit^{1,5}, Sophie Cassaignon^{*2,3,4,5}

Highlights:

Highly pure TiO₂-B and Fe-TiO₂-B were synthesized via a novel soft chemistry approach

The fast microwave-assisted synthesis allows facile scale-up of the process

Microwaves reduce the reaction time by about 95 % and increase cost-effectiveness

Fe-TiO₂-B allows enhancing capacity and rate capability in lithium batteries
