Abstract

This paper examines the relationship between opacity and the cost of intermediation in Asian banks. Using a sample of publicly traded commercial banks from 2002 to 2008, our empirical results show that higher opacity is associated with a lower intermediation cost in banking. Hence, bank managers in their efforts to overcome asymmetric information issues and to improve transparency tend to offset the higher cost of acquiring and disclosing information by increasing the cost of intermediation for entrepreneurs. Moreover, a deeper look at the country level indicates that the negative link between opacity and the cost of intermediation is reversed as globalization increases. Greater globalization therefore outweighs managerial entrenchment behavior to preserve bank opacity. Our findings highlight that bank opacity issues are even more costly in countries with higher globalization.

1. Introduction

Financial crises in both developing and developed countries during the last two decades have highlighted the shortcomings of uncontrolled financial liberalization. On the one hand, financial liberalization has led to stronger financial development and has therefore reduced the opaqueness of bank loans, since the availability of credit information regarding borrowers' financial health has increased (Rajan, 2005). Moreover, banks are now allowed to engage in securitization that enables them to accurately price their credit risk, while the development of structured products such as collateralized loan obligations also enables investors and rating agencies to price bank loans. On the other hand, financial development could also have created opportunities for bank managers to engage in more opaque activities, in order to substitute costs of monitoring to reduce asymmetric information related to bank loans (Wagner, 2007).

For instance, in the case of the US, the end of the Glass-Steagall Act in 1999 has brought US banks to engage in off-balance-sheet activities. Wagner (2007) points out that the unused commitments of US commercial banks as a share of total assets have increased from 37% to 64% over the last two decades. The share of long-term loans in total loans in US banks has also increased from 15% to 25% in the same period². In parallel, US banks have experienced a substantial increase in non-interest income as documented by Stiroh (2004) with a share of non-interest income in total income growing rapidly from 19% in 1980 to 43% in 2004.

In countries with stricter restrictions on off-balance-sheet activities, it is rather difficult for banks to substitute their costs of acquiring and disclosing information on bank assets by engaging in off-balance-sheet activities. Such banks can thus offset their costs by increasing the intermediation cost (higher loan rates charged to borrowers and/or lower deposit rates). Meanwhile, whether or not promoting greater transparency has an impact on the intermediation cost in banking is an important issue that has, to our knowledge, not been examined before. This paper fills this gap in the literature by focusing on Asian countries where restrictions on off-

² Long-term loans are typically more opaque than short-term loans, because borrowers' financial health is rather difficult to measure over a longer horizon (Wagner, 2007). Some studies also highlight that an overall increase in bank opacity typically occurs in the long-run period. Morgan (2002) documents that the opacity of US banks relative to that of non-bank institutions in the US has increased from 92% in 1983 to 109% in 1993. For European banks, Iannotta (2004) also points out that their opacity relative to non-bank institutions has increased from 82% in 1993 to 100% in 2003.

balance-sheet activities are still high and the share of non-interest income activities rather limited (Agusman et al., 2008; Adams, 2008).

Specifically, we aim to test whether bank managers' efforts to reduce opacity may be beneficial or detrimental for financial intermediation in Asian countries. Moreover, we also extend our analysis to examine whether the link between bank opacity and the intermediation cost is dependent on the level of institutional development. Indeed, institutional development has impacted the extent to which Asian countries have suffered from the 1997 Asian crisis which in turn has affected intermediation activities in those countries. For instance, Furman and Stiglitz (1998) document that Asian countries with weaker institutional development, such as Indonesia and Thailand, were severely affected by the 1997 Asian crisis.

Our focus on the link between bank opacity and the intermediation cost in Asian countries is motivated by the following reasons. It is generally admitted that asymmetric information has contributed to exacerbate financial instability in Asia which triggered the 1997 Asian crisis (Sau, 2003). In order to prevent financial crises in the future, reducing asymmetric information is therefore necessary. Surprisingly, previous literature has not examined the issue of whether reducing asymmetric information or promoting information transparency in banking has an impact on real economic activities stemming from movements in bank intermediation cost.

Meanwhile, the banking sector remains a major source of finance for firms in Asian countries and therefore examining the ways to promote intermediation is essential in fostering economic growth in Asian countries (Adams, 2008). Yet, Asian banking has developed rapidly since the end of the 1997 crisis. Cross-border mergers and acquisitions involving Asian banks have increased from US\$ 2.5 billion during 1991-1995 to US\$ 65 billion during 2001-2005 (Domanski, 2005; Moshirian, 2008). As the financial sector has rapidly grown in Asian countries, assessing the link between bank opacity and the intermediation cost has become an important issue because financial development exacerbates bank managers' incentives to preserve the opacity of bank assets (Wagner, 2007). Consequently, it is important to examine whether such managerial entrenchment leads to a higher intermediation cost.

The rest of this paper is structured as follows. Section 2 presents our research focus and relates it to previous literature. Section 3 describes the data, variables and methodology used in

this study. Section 4 discusses empirical findings and provides some robustness checks, while Section 5 concludes the paper.

2. Related literature and research focus

The role of the banking sector in supporting economic growth has been widely explored and this issue is still broadly debated. Bencivenga and Smith (1991) are the first to demonstrate that the presence of banks as financial intermediaries enhances long-run economic growth because banks can optimize depositors' funds to boost long-term savings and investments. In contrast, a large number of papers also indicate the presence of threshold effects. Hence, the link between financial intermediation and development is not necessarily positive (e.g. Augier and Soedarmono, 2011; Deidda and Fattouh, 2002; Bose and Cothren, 1996 & 1997)³.

As a matter of fact, the presence of asymmetric information is one of the factors that make the link between finance and development rather ambiguous. The financial intermediation approach developed by Diamond (1984) shows that bank loans are opaque and hence, the cost of monitoring to reduce asymmetric information in bank loans can affect financial intermediation *via* its impact on the lending rate. In a similar vein, Bose and Cothren (1997) show that banking development can enhance capital accumulation and long-run growth, when the cost of acquiring information from screening activities falls below a threshold level. This result can be further interpreted that the expertise of banks in overcoming asymmetric information plays a critical role in making the economy move toward a credit screening equilibrium rather than a credit rationing equilibrium.

The empirical literature shows that the extent of asymmetric information strongly affects the development and the stability of the banking sector. Tsai et al (2011) show that banks are more likely to expand operations in countries with a credit reporting bureau, where shared credit reports are of better quality in terms of timeliness, accuracy and completeness. Banks are thus likely to expand in countries with lower asymmetric information. In parallel, the stock market also suffers from asymmetric information between lenders and borrowers. Hence, financial liberalization that fosters stock market development too rapidly can exacerbate asymmetric

³ See Levine (2005) for a comprehensive literature review on the finance-growth nexus.

information and deteriorate bank stability ending up in banking crises (Bhide, 1993; Demirgüç-Kunt and Detagriache, 1999).

From these studies, it is indeed clear that the presence of asymmetric information plays a significant role in affecting financial development and stability. However, there is no previous study that provides empirical evidence on the impact of asymmetric information in banking on economic activities in particular. The present paper attempts to contribute in this direction. Specifically, we build on the work of Bose and Cothren (1997) and Wagner (2007) to examine the link between asymmetric information and the cost of intermediation in banking.

According to Bose and Cothren (1997), the extent to which bank assets are opaque determines the cost of acquiring information which in turn determines capital stock accumulation. In the present paper, instead of focusing on capital stock accumulation and economic growth, we examine whether bank managers in their efforts to overcome asymmetric information, tend to offset higher cost of acquiring and disclosing information by increasing the intermediation cost for entrepreneurs. In other words, we test the link between bank opacity and the intermediation cost. As further contributions, we also examine whether the link between bank opacity and intermediation cost is country-specific.

Poghosyan (2013) highlights that institutional development plays a crucial role in affecting the cost of bank intermediation. Lower institutional quality is found to increase the intermediation cost. Building on this work, we test whether institutional development matters in affecting the link between opacity and the intermediation cost in banking. Given that our study focuses on the role of informational transparency, we therefore emphasize on institutional development related to the degree of countries' openness that integrates information-sharing activities. We use the globalization index developed by Dreher et al. (2008) as a proxy of institutional development that contains a measure of economic globalization, political globalization, and social globalization which include transparency in terms of information flows. Dreher et al. (2008) empirically show that the overall index of globalization is indeed positively associated with economic growth.

3. Data, variables and methodology

3.1. Data sources

In order to assess the link between opacity and the intermediation cost in banking, we use several sources of data. Bank-level data are retrieved from BankScope Fitch IBCA. Only publicly traded banks (i.e. listed on a stock exchange) are considered in this study because our framework requires the use of data on bank stock prices. Due to such restrictions, our sample consists of an unbalanced panel of 253 listed commercial banks for the 2002-2008 period that operate in 13 Asian developed and developing countries⁴. These countries include China (14), Hong Kong (6), Japan (87), South Korea (7), Taiwan (12), Indonesia (25), Malaysia (4), Philippines (12), Singapore (3), Thailand (11), Pakistan (23), India (40), and Sri Lanka (9).

We consider daily stock price data for each bank in our sample and also the daily global market indices at the country level. Such market data come from Thomson Datastream International. For deeper insights on whether the link between opacity and the intermediation cost in banking depends on the quality of institutions, we also retrieve the index of globalization (*GLOBAL*) from Dreher et al (2008) as a proxy of institutional development to reflect the degree of openness in various aspects including the economic, social and political dimensions. To construct our macroeconomic control variables, we retrieve data from International Financial Statistics provided by the International Monetary Fund, except for the ratio of bank concentration (*CONC*) which is retrieved from Beck and Demirgüç-Kunt (2009).

3.2. Bank intermediation cost

In order to measure the bank intermediation cost, we consider the ratio of net interest income to total assets or net interest margin (*NIM*). *NIM* is widely used as a proxy of bank intermediation cost in the previous literature (e.g. Demirgüç-Kunt et al, 2004; Demirgüç-Kunt and Huizinga, 1999; Dabla-Norris and Floerkeimer, 2007; Naceur and Kandil, 2009). Banks' net interest margin can be considered as a price markup to offset higher costs related to banking operations in lending, monitoring and deposit activities. Higher net interest margin implies that banks are likely to experience a higher intermediation cost which they in turn transfer to their

⁴ The choice of countries included in our sample builds on Soedarmono et al. (2013), and Agusman et al. (2008) who study Asian banks, except that we add Japan and China. The values in parentheses are the number of banks.

customers (higher loan rates for borrowers and/or lower rates for depositors). Following Demirgüç-Kunt et al. (2004), we also consider the ratio of overhead cost to total assets (*OVER*) as an alternative proxy of the bank intermediation cost.

Some papers consider that higher net interest margins merely reflect higher profitability in banking instead of higher intermediation cost charged to borrowers (e.g. Naceur and Kandil, 2009; Naceur and Oman, 2011). For robustness considerations, we build another measure to capture the intermediation cost. More precisely, we consider a net interest margin measure which is adjusted for profitability (*RNIM*). This measure reflects a markup price that “purely” captures the motivation of bank managers to offset costs of banking operations which are in turn positively associated with the bank's intermediation cost, i.e. the margin charged to borrowers. *RNIM* is computed using the residual terms of an Ordinary Least Squares (OLS) regression of *NIM* on both return on assets (*ROA*) and return on equity (*ROE*)⁵. Accordingly, *RNIM* captures movements in the net interest margin that are not influenced by changes in bank profitability. Overall, higher *NIM*, *RNIM* and *OVER* are all associated with a higher intermediation cost in banking.

3.3. Bank opacity

We assess the degree of bank opacity using an indicator of bank stock price synchronicity (*SYNC*). Previous empirical studies support the use of stock price synchronicity to account for the extent of information reflected in stock prices and hence, determining firms' transparency. Roll (1988) documents that the weak relationship between firms' stock price and market price movements is due to the fact that more firm-specific information can be reflected in individual firms' stock prices. In other words, the relative amounts of firm-specific information incorporated in stock prices determine whether or not individual firms' stock prices move together in the same direction with the stock market index.

If firm-specific environments (e.g. firms' disclosure policies, analyst reports, or institutional factors including property rights protection, the quality of government and legal origin) cause individual firms' stock prices to aggregate more firm-specific information, stock price synchronicity should be lower (Morck et al, 2000; Durnev et al., 2003; Chan and Hameed,

⁵ *ROA* is the ratio of net income to total assets, while *ROE* is the ratio of net income to total equity.

2006; Jin and Myers, 2006; Piotroski and Roustone, 2004). In this case, R -squared from a standard market model that reflects a firm's stock return synchronicity should be lower, while firm-specific return variation should be higher. By extension, a firm's transparency tends to be higher in this regard (Jin and Myers, 2006).

Following Chan and Hameed (2006), we compute opacity ($SYNC$) using stock price synchronicity which is estimated from a standard market model defined as follows:

$$r_{ijs} = \alpha_i + \beta r_{js}^m + \varepsilon_{is} \quad (1)$$

From Equation (1), r_{ijs} is the stock return on bank i in country j on day s , while r_{js}^m is the daily market return computed on the basis of domestic market indexes in country j on day s . Both variables are defined as follows:

$$r_{ijs} = \log \left[\frac{p_{ijs}}{p_{ijs-1}} \right]$$

$$r_{js}^m = \log \left[\frac{p_{m(j),s}}{p_{m(j),s-1}} \right]$$

Accordingly, p_{ijs} is the stock price of bank i in country j on day s , while $p_{m(j),s}$ is the global market price index in country j on day s .

In the next stage, we run regressions from 2002 to 2008 to estimate Equation (1) using the OLS method following Bautista et al (2009). For each year, we eliminate banks with trading days less than 70% of the total number of trading days per year. As such, we obtain the annual R^2 from bank stock i in country j at year t . Given the bounded nature of R^2 between zero and one, we then apply a logistic transformation. The degree of bank synchronicity is thus defined as

$$SYNC_{ijt} = \log \left[\frac{R_{ijt}^2}{1 - R_{ijt}^2} \right] \quad (2)$$

From Equation (2), a higher R^2 reflects higher bank stock price synchronicity ($SYNC$), i.e. the stock price predominantly moves in the same direction as the global market index. In such a case, the weaker bank-specific information content can be incorporated in the bank stock price

and hence, bank-level information disclosure in bank stock prices is also weaker because of stronger opacity problems.

To our best knowledge, prior studies on firm transparency mainly have mainly focused on non-financial firms (e.g. Ball, 2001; Bushman and Smith, 2001; Chan and Hameed, 2006; Gul et al., 2010). Although the need for bank transparency to strengthen market discipline is widely recognized (Flannery, 1998), only Francis et al (2012) have examined the determinants of stock return synchronicity in the banking industry. We hence contribute to the scarce literature looking at stock price synchronicity to account for opacity in banking..

Nevertheless, several studies also cast doubts on the use of bank stock price synchronicity as a valid measure to assess the extent to which firms are transparent (e.g. Dasgupta et al., 2010; Ashbauh-Skife et al., 2006). As a validity check, we follow Gul et al. (2010) to test whether stock price synchronicity can ascertain the extent to which banks are transparent or opaque. In doing so, we build the following regression model:

$$MAR_{ijt} = \beta_0 + \beta_1 NI_{ijt} + \beta_2 NI_{ijt} * SYNC_{ijt} + \beta_3 NI_{ijt} * EQTA_{ijt} + \beta_4 NI_{ijt} * MTBV_{ijt} + error \quad (3)$$

MAR is the market-adjusted bank stock return measured by the difference between annualized bank stock returns and annualized capital market returns. *NI* is the ratio of net income to the market value of equity. *EQTA* and *MTBV* represent the ratio of total equity to total assets, and the market-to-book-value ratio, respectively. Meanwhile, *NI*EQTA* and *NI*MTBV* are control variables as used by Gul et al. (2010). To estimate Equation (3), we include both individual and time-fixed effects. *SYNC* can be considered as a valid measure of bank opacity when β_1 is positive but β_2 is negative. This suggests that capital markets can attach higher value to earnings, but only in banks with lower synchronicity. As synchronicity becomes higher, the positive link between *NI* and *MAR* is reversed. Opacity problems therefore occur because earnings information capitalized into stock prices becomes lower in high-synchronicity banks.

3.4. Control variables

To control for other factors that explain movements in the bank intermediation cost, control variables representing both bank-specific and country-specific factors are incorporated in

the regressions. For bank-specific control variables, we consider the ratio of total equity to total assets (*EQTA*), the ratio of loan loss provisions to total loans (*LLP*), the loan-to-deposit ratio (*LDR*) and the logarithm of banks' total assets (*SIZE*). To control for differences in the macroeconomic environment and market structure, we consider three indicators which are the bank concentration ratio measured by the share of the three largest banks' total assets in the banking system's total assets (*CR3*), the growth rate of real per capita income (*GDPG*), and the inflation rate (*INF*).

Higher *EQTA* is likely to increase bank net interest margin because of a decline in funding costs, since higher *EQTA* can reduce bank default risk which in turn decreases funding costs (Demirgüç-Kunt et al, 2004). *LLP* and *LDR* are incorporated to account for credit risk and intermediation activities, respectively. Banks with higher credit risk are expected to charge a higher lending rate resulting in a higher intermediation cost. Meanwhile, as higher *LDR* is associated with more lending activities, higher loan-to-deposit ratio is expected to increase the intermediation cost because banks tend to offset higher monitoring costs related to lending activities. In addition, *SIZE* is also included to control for "too-big-to-fail" effects that might affect banks' loan pricing behavior. However, the expected sign of the link between *SIZE* and the intermediation cost is ambiguous. Larger banks could charge lower rates because they do not fear distress. They can also benefit from lower funding cost (lower deposit rates) because of higher confidence from depositors (higher bail-out probability).

With regards to macroeconomic control variables, a higher bank concentration ratio (*CR3*) is expected to increase the bank intermediation cost because banks in concentrated markets are able to charge higher lending rates (Demirgüç-Kunt et al., 2004). Moreover, considering economic growth (*GDPG*), which is standard in the literature is also important in order to reflect business cycle movements. Changes in economic growth are expected to change business opportunities for banks. However, the sign of the link between economic growth and the intermediation cost is unclear, since it depends on banks' expertise in dealing with changes in the business cycle. Finally, we also control for the inflation rate (*INF*) because a higher inflation rate can lead to a higher bank net interest margin as shown by Huybens and Smith (1999).

3.5. Methodology

Our analysis is conducted in several stages. In the first stage, we compute a measure of bank stock price synchronicity (*SYNC*). In the second stage, a validity check is conducted using Equation (3) to ensure that *SYNC* can be used to assess the degree of bank opacity. In the next turn, the link between bank opacity and intermediation cost is empirically examined.

Once the general results are obtained, we further examine whether the degree of globalization at the country level alters the link between bank opacity and intermediation cost. For this purpose we interact *SYNC* with the index of globalization (*GLOBAL*) and focus on the coefficient of *SYNC*GLOBAL*. The index of globalization (*GLOBAL*) indicates the extent to which countries are open in terms of economic, political and social dimensions that integrate information-sharing activities in those countries. *GLOBAL* is the overall index of globalization or the KOF Index of Globalization developed by Dreher et al. (2008) which integrates all aspects of globalization, i.e. social, economic and political dimensions of globalization.

In terms of econometric methodology in examining the link between opacity and the intermediation cost in banking, we use a dynamic panel model. Recent studies on the determinants of bank performance recommend the use of dynamic panel data methodology (e.g. Naceur and Kandil, 2009; Naceur and Omran, 2011), since the current intermediation cost can be affected by its past values due to managerial anticipation or learning. Hence, the use of a dynamic panel model is more relevant than a static panel model to capture such possible behavior i.e. to control for a possible autoregressive process in the bank intermediation cost variable. Nevertheless, our concern in this study is more to examine the impact of bank opacity on the intermediation cost rather than the speed of adjustment of the bank intermediation cost.

Accordingly, we test the following models. Equation (4) is to test the impact of bank opacity (*SYNC*) on the intermediation cost (*COST*), while Equation (5) is to test whether such a relationship is dependent on the degree of globalization at the country level, respectively⁶.

$$\begin{aligned}
 COST_{ijt} = & \beta_0 COST_{ijt-1} + \beta_1 SYNC_{ijt} + \beta_2 EQTA_{ijt} + \beta_3 LLP_{ijt} + \beta_4 LDR_{ijt} \\
 & + \beta_5 SIZE_{ijt-1} + \beta_6 CR3_{jt} + \beta_7 GDPG_{jt} + \beta_8 INF_{jt} + error
 \end{aligned} \tag{4}$$

⁶ *COST* represents a set of dependent variables that capture the bank intermediation cost. These include *NIM*, *OVER*, and *RNIM*.

$$\begin{aligned}
COST_{ijt} = & \beta_0 COST_{ijt-1} + \beta_1 SYNC_{ijt} + \beta_2 SYNC_{ijt} * GLOBAL_{ijt} + \beta_3 GLOBAL_{ijt} \\
& + \beta_4 EQTA_{ijt} + \beta_5 LLP_{ijt} + \beta_6 LDR_{ijt} + \beta_7 SIZE_{ijt} + \beta_8 CONC_{jt} \\
& + \beta_9 GDPG_{jt} + \beta_{10} INF_{jt} + error
\end{aligned} \tag{5}$$

In estimating all the regressions, we follow Arellano and Bover (1995) and Blundell and Bond (1998) using the two-step generalized method of moments (GMM) estimator or the System GMM. The System GMM is the extension of the Standard GMM developed by Arellano and Bond (1991), where the first-differenced equation is combined with the level equation in order to produce better outputs than the Standard GMM (Baltagi, 2005). This combination is essential, particularly when variables are close to a random walk. In running the System GMM, we also consider finite sample corrections proposed by Windmeijer (2005) to ensure that our estimated coefficients are robust. Since our dynamic panel data models contain an autoregressive variable, we account for the orthogonal deviation transformations of instruments to control for possible bank-level fixed effects. Overall, the System GMM is valid if AR (2) test and Hansen-J test are both insignificant. This indicates that there is no second-order autocorrelation among errors of first-differenced equation, and our identifying restrictions are valid, respectively.

On the whole, all the estimations from Equation (3) to Equation (5) are conducted separately for two different bank samples. The first sample includes all the banks operating in the considered 13 Asian countries. Meanwhile, the second sample excludes, as a robustness check, Japanese banks which dominate our sample, to ensure that our results are not affected by Japanese banks' characteristics.

4. Empirical results

In Table 1, we present descriptive statistics for all the variables used in this study. We also impose restrictions to the ratio of total equity to total assets (*EQTA*) to eliminate possible outliers. Specifically, we eliminate values in *EQTA* that are lower than zero. Banks with negative *EQTA* may not fully operate in the market because they may require assistance from bank regulators or the lender of last resort.

[Insert Table 1 here]

Moreover, Table 2 presents the correlation structures of all the variables used to analyze the link between opacity and intermediation cost in banking. It shows that the independent variables included in Equations (4) and (5) are not strongly correlated and hence, that our regressions do not suffer from multicollinearity issues.

[Insert Table 2 here]

Given that the previous literature cast doubts on the use of bank synchronicity as a measure of bank opacity, we test whether bank stock price synchronicity can be a valid proxy of bank opacity. Table 3 presents the empirical results for Equation (3). The ratio of net income to the market value of equity (NI) has a positive and significant relationship with the market-adjusted return of banks (MAR). Such a relationship is however reversed for $NI*SYNC$, suggesting that higher $SYNC$ reduces the likelihood of the market to attach a higher value to bank earnings. In this regard, $SYNC$ reflects the extent to which banks may suffer from opacity problems. These results hold for both the overall bank sample and the non-Japanese bank sample.

[Insert Table 3 here]

To ensure the robustness of our results, we repeat estimations for Equation (3) by replacing MAR with BSR which represents the annualized bank stock return. It appears that higher NI is still associated with higher BSR , particularly for low-synchronicity banks. For high-synchronicity banks, the positive relationship between NI and BSR is reversed, supporting the notion that higher synchronicity precludes the incorporation of bank-specific information into bank stock prices. High-synchronicity banks are thus more likely to suffer from opacity problems than low-synchronicity banks. These results remain unaltered when we include or exclude Japanese banks from our estimations.

From the above discussion, our indicator of bank synchronicity can be considered as a valid proxy to assess the degree of bank opacity. Table 4 then presents our empirical results with regards to the impact of bank opacity on the intermediation cost for the overall bank sample and the sample from which Japanese banks are excluded.

[Insert Table 4 here]

For the overall bank sample, we document that higher bank opacity is associated with a lower intermediation cost measured by *NIM* or *RNIM*. Our dynamic panel data models are also valid, given that the AR (2) test and the Hansen-J test are not rejected at least at the 5% level. These findings still hold when we exclude Japanese banks from our sample. Our findings are therefore consistent with the notion that disclosing and sharing information is costly due to managerial entrenchment effects. Since bank managers tend to preserve the opacity of banks' assets as in Wagner (2007), low-synchronicity (or transparent) banks are more likely to exhibit a higher intermediation cost than high-synchronicity (opaque) banks. Accordingly, the managers of transparent banks tend to offset costs of acquiring and disclosing information by increasing the cost of credit for entrepreneurs due to the entrenchment effect. On the other hand, higher transparency can also reduce the cost of bank deposits because of higher confidence of bank depositors. In this case as well, the cost of intermediation may in turn increase, although the cost of credit does not increase.

When we consider the role of the degree of globalization (*GLOBAL*), we find that the negative impact of bank opacity on the intermediation cost is more pronounced in countries with lower globalization. As globalization at the country level increases, the negative link between bank opacity and intermediation cost is reversed, especially when we use *NIM* or *OVER* as a proxy of the bank intermediation cost as shown in Table 5. The negative coefficient on *SYNC* is more than outweighed by the positive coefficient on *SYNC*GLOBAL* (the absolute value of the coefficient of *SYNC*GLOBAL* is higher than the absolute value of the coefficient of *SYNC*). An increase in *SYNC* will lead to a decrease in the cost of intermediation if the value taken by *GLOBAL* is very low, but to an increase in the cost of intermediation for higher values taken by

*GLOBAL*⁷. We lose a substantial number of observations in this stage because Dreher et al. (2008) do not provide data on globalization indices for Hong Kong and Taiwan, and our sample incorporates publicly-traded commercial banks from both countries. But in Table 5, our dynamic panel data models remain valid, since AR (2) test and Hansen-J test are not rejected, at least at the 5% level.

[Insert Table 5 here]

In countries with greater globalization, bank opacity might increase the cost of intermediation possibly because of the following reasons. Countries with greater globalization have greater openness in terms of economic, political and social dimensions and hence, demand for greater transparency in various aspects tends to be higher. With regards to banking activities, agents from such countries are also likely to require information of better quality and better financial services. Consequently, banks with higher opacity problems in countries with greater globalization tend to face higher demand for transparency which may in turn outweigh bank managerial entrenchment effects to preserve opacity. In turn, the bank intermediation cost might be positively linked with opacity in countries with greater globalization. In order to enhance financial intermediation, efforts to improve bank-level transparency are therefore necessary in such countries.

Furthermore, because bank opacity problems can also exacerbate asymmetric information issues that could possibly lead to financial instability (Sau, 2003), efforts to increase bank-level transparency in countries with lower globalization remain important. However, bank regulators in countries with lower globalization need to deal with managerial entrenchment effects by promoting bank-level transparency because bank managers in such countries tend to offset the cost of acquiring and disclosing information by increasing the cost of intermediation.

In the meantime, most of the control variables fulfill our expected signs. *EQTA* as the equity-to-asset ratio has a positive impact on the cost of intermediation. This result remains

⁷ The marginal effect of an increase in *SYNC* is equal to $\beta_1 + \beta_2 GLOBAL_{ijt}$, which for instance in the first equation of table 5 (column 1) is positive for values of *GLOBAL* higher than $0,28793/0,43282 = 0.66524$. In our sample, *GLOBAL* ranges from 0.4616 to 0.8915 (see Table 1).

robust whether or not we exclude Japanese banks from our sample. Higher bank credit risk (*LLP*) is also found to exacerbate the cost of intermediation in both the overall bank sample and the non-Japanese bank sample. Bank size (*SIZE*) is also positively associated with a higher intermediation cost for the overall bank sample and the non-Japanese bank sample. With regards to macroeconomic control variables, a higher bank concentration ratio (*CR3*) and a higher inflation (*INF*) also exacerbate the intermediation cost, while stronger economic growth (*GDPG*) has a negative impact on it. These results hold whether or not we exclude Japanese banks from the sample.

5. Additional robustness checks

Although our empirical results regarding the link between intermediation cost and opacity in banking are robust to different measures of the bank intermediation cost, as well as to different sample definitions that exclude or include Japanese banks, we conduct additional robustness checks to ensure that our results are not biased. First, given that Asian countries differ in terms of the depth of financial markets which may in turn affect the extent to which bank-specific information can be incorporated in bank stock prices, we focus on countries that have similar levels of financial market development. Accordingly, we exclude banks operating in India, Pakistan and Sri Lanka from our sample. Our empirical results remain identical when we ignore these three countries. Higher opacity leads to a lower intermediation cost in banking, but this relationship is reversed as globalization at the country-level increases.

Second, Dreher et al. (2008) do not provide globalization data on Hong Kong and Taiwan and hence, we also exclude banks from these two countries. Our results are unaltered, with higher opacity leading to higher intermediation cost in banking.

Third, as we only consider listed banks in our study, which are more likely to be categorized as large banks in their countries, we exclude *SIZE* from the control variables as stated from Equation (4) and (5). Using this new specification does not alter our empirical results.

Finally, we exclude the year 2008 to eliminate the possible effects of the 2008 global financial crisis. We thus conduct regressions for Equation (4) and (5) using the 2002-2007 period and still find a negative link between opacity and the intermediation cost. In addition, in

countries with greater globalization, the negative link between opacity and the intermediation cost in banking is still reversed.

6. Conclusion

Using a sample of publicly traded commercial banks in 13 Asian countries, this paper examines how bank opacity is valued by bank managers through its relationship with the cost of bank intermediation. Our empirical results reveal that higher opacity is associated with lower intermediation cost in banking. This result provides empirical support for the theoretical work by Wagner (2007) who argues that bank opacity is positively valued by bank managers who tend to preserve it. Similarly, we also provide empirical support for the theoretical model built by Bose and Cothern (1997) who find that bank managers, in their efforts to alleviate asymmetric information and enhance transparency, tend to offset the cost of acquiring and disclosing information by increasing monitoring costs that in turn hinders economic growth.

Nevertheless, the negative link between bank opacity and the intermediation cost is also conditional on the degree of globalization at the country level. In countries with greater globalization, the negative link between bank opacity and the intermediation cost is reversed. Greater globalization therefore seems to outweigh the managerial entrenchment to preserve bank opacity. As such, higher bank opacity leads to a higher bank intermediation cost in countries with greater globalization. These findings show that managerial entrenchment effects that lead to greater incentives for bank managers to preserve bank opacity are more likely to occur in countries with lower globalization.

On the whole, our findings highlight the importance of bank transparency to promote better financial intermediation, particularly in countries with greater globalization. Efforts to enhance bank transparency in less globalized countries is also important. However, bank regulators in less globalized countries need to consider mechanisms to overcome bank managerial entrenchment because bank managers' efforts to enhance bank-level transparency can exacerbate the intermediation cost.

Source and note: Authors' calculation. The definition of variables follows Table 1. Dynamic panel data models use the two-step GMM dynamic panel estimators with Windmeijer's robust finite sample correction, taking into account the orthogonal deviation transformations of instruments. Dynamic panel data models are valid if *AR(2)* test and *Hansen-J* test are not rejected. Standard errors are in parentheses. ***, **, * indicate significance at the 1% , 5% and 10% levels, respectively.
