- A magnetic anisotropy of the ferromagnetic Ni nanowires was observed.
- The P(VDF–TrFE) glass transition has an influence on the NWs Ni/P(VDF–TrFE) 0.3% vol composite magnetic properties.
- The NWs Ni/P(VDF–TrFE) composite was polarized to obtain a significant piezoelectric coefficient of 7 pC N^{-1} .
- The magnetoelectric coefficient reached the high value of 237 V/(m Oe) .

A B S T R A C T

Multiferroic composites with very high magnetoelectric coupling composites have been elaborated by incorporating high aspect ratio magnetic nickel particles in a ferroelectric matrix P(VDF–TrFE). Nickel nanowires (NWs) were elaborated by the electrodeposition method which allows obtaining a constant aspect ratio of 250. SEM-FEG images showed a Ni NWs homogeneous dispersion in acetone or in the P(VDF–TrFE). HR-TEM images and electronic diffraction studies revealed that the Ni NWs are monocrystalline, thanks to the electrodeposition method. Magnetic measurements showed a strong anisotropy of the magnetic particles, the coercivity is higher in the parallel direction (160 Oe). This anisotropy decreased for the composites due to the diminution of the Ni NWs interactions. The piezoelectric coefficient obtained after the composite polarization was significant (7 pC N^{-1}) under a polarization field of 60 kV mm^{-1} . The magnetoelectric coefficient reached the value of 237 V/(m Oe) at 4 kHz. According to the previous studies, this value is the highest one found for multiferroic polymer matrix composites.

1. Introduction

Magnetoelectric effect (ME) is the combined properties of magnetostriction (MS) and piezoelectricity (PE) behavior [1,2]. By coupling these both properties, it is possible to perform a change of electric polarization upon applying magnetic field (direct ME effect) or, in return, to obtain a change of magnetization under an electric field (indirect ME effect) [3,4]. Two ways have been explored: the intrinsic one with multiferroic materials and the extrinsic one with magnetoelectric composites. Preparation and characterization of ME multiferroic materials have attracted much

interest in research for functionalized materials and devices. They have been widely used as data storage devices [5,6], magnetic sensors, transducers and actuators [7]. The previously elaborated composites which present the higher ME coefficients are mostly for ceramic composites. For example, a multilayer composite terfenol-D/PZT/terfenol-D has an ME coefficient of 600 V/(m Oe) [8], another multilayer composite Ni/PZT/Ni has 150 V/(m Oe) [9], all measured at resonance frequency. These composites are made of a piezoelectric material and a magnetostrictive material. This extrinsic approach, ferromagnetic particles in organic ferroelectric matrix, could lead to revolutionary device applications due to their intrinsic low-cost, lightweight, and flexible features [10]. In previous works, ferroelectric matrices have been used to elaborate ME composites as multilayers [10–12] and 3-0 composites where

particles are dispersed in a matrix [13,14].

Recently, magnetic nanowires have been widely studied because of their promising applications in the perpendicular and parallel measurement direction [15–17]. One promising technic to elaborate such magnetic nanowires is the electrodeposition [18–21]. During the process, the lateral growths of deposited ferromagnetic materials are bounded by the pore walls so as to form the desired nanowire arrays.

In this work, ferromagnetic Ni nanowires (NWs) will be prepared by electrochemical deposition in an anodic aluminate oxide (AAO) porous template. This method allows obtaining 250 aspect ratio NWs with negligible size dispersion. They will be introduced in a ferroelectric organic matrix P(VDF–TrFE) in a concentration of 0.3 vol%. Ferromagnetic and ferroelectric properties will be studied for Ni NWs and neat P(VDF–TrFE). These measurements will also be performed on P(VDF–TrFE)/Ni NWs nanocomposites to determine their ferromagnetic and ferroelectric behavior. The P(VDF–TrFE)/Ni NWs nanocomposite magnetoelectric coefficient will be determined.

2. Experimental

2.1. Materials

Magnetic nanowires (NWs) were prepared by electrochemical deposition in an anodic aluminum oxide (AAO) porous template. The electrolyte used for the deposition was a standard Watts bath with an accurate pH value of 4. Direct current (DC) electrodeposition was carried out at room temperature using a Ni wire as anode with 2.0 mm in diameter. A 200 nm diameter and 50 μm thickness porous AAO membrane was supplied by Whatman. One side of the AAO membrane was coated with a 35 nm thickness silver layer by using sputtering technique as cathode for electrodeposition. The NWs growing was controlled by the time deposition and the direct current intensity using a Keithley 2420 source meter. The AAO filled membrane was dissolved in NaOH solution (6 M) for 30 min, releasing the NWs from the template. The NWs were washed with distilled water, filtrated and well dispersed in acetone under sonication for 5 s, corresponding to a dissipated power of 25 W.

Poly(vinylidene fluoride–trifluoroethylene) P(VDF–TrFE) (70/30) mol% copolymer was supplied by Piezotech S.A. (Hésingue, France).

2.2. P(VDF–TrFE)/Ni NWs composites elaboration

The nanocomposites were prepared by using solvent casting method. P(VDF–TrFE) was dissolved in acetone under magnetic stirring at 80 °C for 1 h. The Ni NWs acetone suspension was poured into the polymer solution and the mixture was submitted to 5 s short pulse of sonication, corresponding to a dissipated power of 25 W. The obtained suspension was precipitated with water. The obtained composite was placed in a steam at 80 °C in order to remove the totality of the solvent. The composite was pressed at 200 °C under a pressure of about 0.3 MPa. 80 μm thickness films were obtained. No solvent residue was found by thermogravimetric analysis, indicating a complete removal of solvent from samples. P(VDF–TrFE)/Ni NW nanocomposites were elaborated with a volume fraction of 0.3 vol%. This is the highest concentration of Ni NWs to get an insulating material that can be macroscopically polarized in our case.

2.3. Scanning electron microscopy

The morphology of Ni NWs was examined by scanning electron microscopy (SEM) using a JEOL JSM 6700F instrument equipped

with a field emission gun (SEM-FEG). The composites were fractured at the liquid nitrogen temperature for observation by SEM-FEG.

2.4. High resolution transmission electron microscopy

The structure and texture of Ni NWs crystallinity were determined by high resolution transmission electron microscopy (HRTEM). Ni NWs were dispersed in toluene and drop of the suspension was coated with lacey carbon films to obtain transparent sample for electron irradiation. TEM and HRTEM images were obtained by using a JEOL 2100F microscope. The diffraction patterns were obtained using the selected area electronic diffraction (SAED) mode.

2.5. Magnetic properties characterization

The measurements were performed with an MPMS 5 Quantum Design magnetometer (cryo-magnet 5 T and cryostat allowing sample temperatures from 2 K to 400 K). The sample is placed between the detection coils in a 5 mm diameter straw, parallel or perpendicular to them and fixed with a cotton wire.

2.6. Polarization and piezoelectric coefficient measurement

The samples were placed between two conductive electrodes and poled by applying a sinusoidal voltage (-55 kV mm^{-1} or $+55 \text{ kV mm}^{-1}$) between the two electrodes.

When a macroscopic polarization is obtained, the piezoelectric coefficient d_{33} is measured by a PM 200 piezometer from Piezotest. A sinusoidal strength is applied during the measurement. The d_{33} is a given by the following equation:

$$d_{33} = \frac{\Delta P_3}{\Delta \sigma_3} \quad (1)$$

where ΔP_3 is the measured polarization and $\Delta \sigma_3$ the applied stain.

2.7. Magnetoelectric measurements

To measure the magnetoelectric current, the sample is placed under a dynamic and a static magnetic fields [22]. The alternative magnetic field H_{ac} is generated by a Helmholtz coil supplied by an audio amplifier (STA-700 Power Amplifier) which is led by a function generator (Agilent 33220A). The permanent magnetic field H_{dc} is created by two electromagnets. Under the magnetic field, the sample is deformed and generates a current amplified by the current amplifier (Keithley 617) and observed on the oscilloscope. The magnetic field generated by the Helmholtz coils is measured by a Hall effect probe (Gauss/Teslameter, F.W. Bell Model 5080).

This measurement permits to calculate the ME coefficient α_E using ME theory. The ME materials equation of state is a second order equation:

$$P = \epsilon E + \alpha_p H + \frac{1}{2} \beta H^2 \quad (2)$$

where P, E, H and ϵ are the polarization, the electric field, the magnetic field and the material permittivity respectively. α_p and β are linear and bilinear polarization ME coefficients respectively. The electric field being inexistent, (2) becomes:

$$P = \alpha_p H + \frac{1}{2} \beta H^2 \quad (3)$$

The ME current is determined by the following equation (4):

$$i = S\dot{P} = \alpha_p S \cdot \left(\overset{\circ}{H}_{dc} + \overset{\circ}{h}_{ac} \right) + \beta S (H_{dc} + h_{ac}) \cdot \left(\overset{\circ}{H}_{dc} + \overset{\circ}{h}_{ac} \right) \quad (4)$$

where S is the electrodes surface in contact with the sample, $S = 15 \times 5 \text{ mm}^2$.

Since $\overset{\circ}{H}_{dc} = 0$, (4) can be written as:

$$i = \alpha_p S \overset{\circ}{h}_{ac} + \beta S (H_{dc} + h_{ac}) \overset{\circ}{h}_{ac} \quad (5)$$

$\overset{\circ}{h}_{ac} = j\omega h_{ac}$ and $h_{ac} = H_{ac} e^{j\omega t}$, (5) becomes:

$$i = \alpha_p S j \omega H_{ac} e^{j\omega t} + \beta S j \omega H_{dc} H_{ac} e^{j\omega t} + \beta S j \omega H_{ac}^2 e^{2j\omega t} \quad (6)$$

If $H_{dc} = 0$, the current evolves linearly with the frequency $i = \alpha_p S j \omega h_{ac}$. The polarization ME coefficient α_p can be determined by measuring i :

$$\alpha_p = \frac{i}{S j \omega h_{ac}} = \frac{dP}{dt} \times \frac{dt}{dH} \quad (7)$$

Physically, α_p expresses the change of polarization relative to the variation of the magnetic field. To compare these data with literature, the stress ME coefficient α_E has to be introduced:

$$\alpha_E = \frac{dE}{dH} = \frac{\alpha_p}{\epsilon_0 \epsilon_r} \quad (8)$$

3. Results

The morphology and aspect ratio of Ni NWs were studied by SEM-FEG using secondary electrons detection mode. Dispersed NWs in acetone suspension are deposited on SEM pin. After acetone evaporation, NWs are shown in Fig. 1a. Fig. 1b presents a bundle of

Ni NWs still bound by the silver layer from the electrodeposition process.

Fig. 1c and d shows SEM-FEG cryofractures of the P(VDF-TrFE) matrix filled with 0.3 vol% of Ni NWs. Films were fractured at liquid nitrogen temperature perpendicularly to the press direction. Using the backscattered electrons detection mode, bright domains show the Ni NWs dispersed in the P(VDF-TrFE) matrix.

The structure and texture of Ni NWs have also been investigated by TEM and HRTEM in Fig. 2. The bright field image (Fig. 2a) shows the morphology of the NWs presenting a homogeneous surface associated with a punctual electronic diffraction. This diffraction pattern and the HRTEM image are characteristic of a monocrystalline NWs. The spacings in the SAED pattern are in good agreement with spacings of the fcc Ni (space group Fm-3m, $a = 3.5239 \text{ \AA}$).

The magnetization hysteresis loops in Fig. 3a were measured at 300 K for Ni NWs embedded in the AAO template at two different magnetic field directions; i.e. parallel (out-of-plane with the AAO template) or perpendicular with the NWs long axis (in-plane with the AAO template) at 2, 100, 300 and 400 K. When the magnetic field is parallel to Ni NWs direction, the NWs coercive field H_C is 160 Oe and the squareness is 0.13, which means that the remnant magnetization M_r is 13% of the saturation magnetization M_s .

P(VDF-TrFE)/Ni NW 0.3 vol% magnetic hysteresis loop at 300 K is represented in Fig. 4b. Although the coercivity H_C equal to 250 Oe is identical in the two magnetic field directions, the squareness value is considerably higher when the magnetic field is parallel with the composite film. The values are 0.65 in the parallel direction and 0.14 in the perpendicular one.

The neat P(VDF-TrFE) and the P(VDF-TrFE)/Ni NW 0.3 vol% composite ferroelectric hysteresis loops were measured and shown on Fig. 4. The applied electric field between the electrodes is strong enough to obtain well-defined hysteresis loops. The neat P(VDF-TrFE) and its composite were submitted to a maximum

Fig. 3. Magnetic hysteresis loop for (a) Ni NWs and (b) the P(VDF-TrFE)/Ni NWs 0.3 vol% at 300 K, H is applied perpendicularly and in parallel to the Ni NWs and the film direction respectively (■) parallel field, (○) perpendicular field.

Fig. 4. Polarization hysteresis loop for neat P(VDF-TrFE) and P(VDF-TrFE)/Ni NWs 0.3 vol%.

electric field of 60 kV mm^{-1} . The remnant polarizations measured when $E = 0$ are $3.9 \text{ } \mu\text{C m}^{-2}$ and $2.5 \text{ } \mu\text{C m}^{-2}$ for neat P(VDF-TrFE) and the P(VDF-TrFE)/Ni NW 0.3 vol% respectively. The coercive field values are 440 kV cm^{-1} and 307 kV cm^{-1} for neat P(VDF-TrFE)

and composite respectively. The piezoelectric coefficient d_{33} has also been measured for the two samples in the direction 3 (perpendicularly to the composite film direction and in parallel to the polarization direction). The values are -20 pC N^{-1}

Fig. 5. Magneto-electric current for P(VDF-TrFE)/Ni NWs 0.3 vol% as a function of H_{ac} at $f = 1 \text{ kHz}$.

and -7 pC N^{-1} for neat P(VDF-TrFE) and P(VDF-TrFE)/Ni NW 0.3 vol% respectively.

The composite ME coefficient has been measured along the direction 3. A H_{dc} scanning showed that the magnetoelectric current I_{ME} is independent from H_{dc} . The following measurements are made with $H_{dc} = 0$. The variation of the ME current I_{ME} has been reported as a function of the magnetic field H_{ac} and the frequency in Figs. 5 and 6 respectively. At this frequency range, I_{ME} increases and evolves linearly with H_{ac} and the frequency. This phenomenon is coherent with the magnetoelectricity theory. If these measurements had been performed close to the resonance frequency, a resonance peak associated with the electromechanical resonance would have been observed [23].

4. Discussion

On the SEM-FEG image (Fig. 1a and b), individual Ni nanowires are observed. They have no affinity with acetone which allows a homogeneous dispersion in this solvent. They were not damaged after sonication treatment. The Ni NWs bundle shows that their lengths are $50 \mu\text{m}$. Their size corresponds to AAO membrane thickness and the size dispersion is insignificant.

Fig. 1c and d shows a Ni NWs uniform distribution throughout the P(VDF-TrFE) matrix and no micron size aggregates are observed. Indeed, Ni NWs have no affinity in acetone and they kept their homogeneous dispersion in the polymer.

Thanks to the bright field TEM image, it is possible to determine Ni NWs diameter. Fig. 2a shows a 200 nm diameter Ni NW. This value confirms the size predicted by the AAO membrane pores diameter. The aspect ratio of Ni NWs was estimated at 250 (using the result of SEM en TEM study). These observations indicate the interest of this method to obtain reproducible Ni NWs.

The SAED pattern (inset Fig. 2a) and the HRTEM image (Fig. 2b) are characteristic of a monocrystalline NW. The spacings in the SAED pattern are in good agreement with spacings of the fcc Ni (space group Fm-3m, $a = 3.5239 \text{ \AA}$).

According to the hysteresis cycle represented in Fig. 3a, a strong anisotropy is evidenced by the both lower H_C (50 Oe) and squareness (0.03) values at the perpendicular field direction to the Ni NWs (out-plane with the AAO template). Such anisotropy has been observed with magnetic nanowires [16,17,24–28] or nanotubes [29,30]. The anisotropy has been previously studied by Han [31] who showed that it was led by three contributions: the shape

anisotropy due to the individual wires which induces a magnetic easy axis (parallel with the wire direction), magnetostatic coupling among the wires which leads to a magnetic easy axis (perpendicular with the wires direction), and the magnetocrystalline anisotropy which induces a parallel magnetic easy axis if the NWs microstructure is monocrystalline. The higher values of coercivity and squareness at the parallel direction show that the magnetocrystalline and the shape anisotropies are predominant over the magnetostatic coupling among the NWs. The coercivity and squareness values are similar to the values found in literature for the same particles diameter [32,33]. Although, we can find higher values in several articles for lower diameter particles [34,35]. Indeed, decreasing the NWs diameter raises coercivity and the magnetic hysteresis hardness [36]. Anisotropy is also observed by studying at the composite magnetic hysteresis loop on Fig. 3. The cryofracture SEM-FEG images (Fig. 1c and d) allow us to observe that the Ni NWs are preferentially oriented in the film direction, due to the hot melt process. The magnetic easy axis is then along the NWs direction. This observation confirms the three contributions previously given. The low NWs concentration in P(VDF-TrFE) induces a magnetostatic coupling decrease which increases the squareness.

Fig. 7 shows the coercivities and the squarenesses of Ni NWs (a) and P(VDF-TrFE)/Ni NW 0.3 vol% composite (b) respectively, as functions of the temperature. The temperature influence of the Ni NWs in alumina template on magnetic properties is negligible. For P(VDF-TrFE)/Ni NW, the composite coercivity decreases when the temperature increases. It has been associated with the polymer mobility increase near T_g (T_g is equal to 240 K for P(VDF-TrFE)). This phenomena has been observed for polyamide 12 filled with Sm-Co particles [37].

The electric hysteresis loops on Fig. 4 show that the remnant polarization and the coercive field values are strongly dependent from the matrix filling. Indeed, the hysteresis loop area is lower for the composite. The higher d_{33} value of the neat P(VDF-TrFE) confirms the difficulty to polarize the P(VDF-TrFE) filled with conductive particles. Nevertheless, the P(VDF-TrFE)/Ni NWs 0.3 vol% d_{33} is significant. In order to know the crystallinity influence on neat P(VDF-TrFE) and its composite d_{33} values, differential scanning calorimetry measurements have been performed with these two samples. The crystallinity of 53.6 and 49.5% for neat P(VDF-TrFE) and P(VDF-TrFE)/Ni NWs 0.3 vol% respectively is considered as constant. It confirms that d_{33} is not dependent from the P(VDF-TrFE) physical structure evolution, but from poling difficulties in presence of Ni NWs (decrease of electrical local field and increase of sample heterogeneity).

Thanks to the equations (7) and (8), the ME coefficient α_E has been calculated and reached the value of $237 \text{ V}/(\text{m Oe})$ at 4 kHz. This value is compared by the ones found in the literature [8,9,38–43] reported in Fig. 8. The ME coupling is due to the strain produced by the magnetic Ni NWs on the piezoelectric matrix. When the NWs are submitted to a magnetic field, they tend to orientate in the direction of the magnetic field due to their anisotropy. This orientation produces a strain on the piezoelectric matrix which is converted in electrical charges. Most of the ME composites in the literature are multilayer which decreases greatly the surface contact and thus the ME coupling. The value obtained for P(VDF-TrFE)/Ni NW composite is in the same magnitude as composites containing PZT. In comparison with composites with a P(VDF-TrFE) matrix the α_E coefficient measured in this work is largely higher. This can be explained by a high surface contact between the ferromagnetic particles and the piezoelectric matrix thanks to a homogeneous dispersion shown in SEM cryofracture. Our high α_E value can also be explained by the Ni NWs high aspect ratio. Previous studies on polymer matrix composites were carried

Fig. 6. Magnetoelectric current for P(VDF-TrFE)/Ni NWs 0.3 vol% as a function of the frequency at $H_{ac} = 1 \text{ Oe}$.

Fig. 8. Comparison of P(VDF-TrFE)/Ni NWs 0.3 vol% magneto-electric coefficient with other composites from the literature [8,9,38–43] with NZCF: $\text{Ni}_{0.3}\text{Zn}_{0.62}\text{Cu}_{0.08}\text{Fe}_2\text{O}_4$; PFNO: $\text{Pb}(\text{Fe}_{0.5}\text{Nb}_{0.5})\text{O}_3$; TeD: Terfenol-D; PZT: $\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$; CFO: CoFe_2O_4 ; TDYF: $\text{Tb}_{0.27-x}\text{Dy}_{0.73-y}\text{Y}_{x+y}\text{Fe}_2$.

out with spherical particles. The NWs ability to deform and the strain implied by the magnetic field are supposed to be more important for high aspect ratio particles than spherical particles.

Contrary to the ceramic based composites, the sample elaborated in this study presents the following advantages: easy elaboration, ductility, low density.

5. Conclusion

P(VDF-TrFE)/Ni NWs 0.3 vol% composites magneto-electric properties are described. At the microscopic level, the magnetic Ni nanowires were quasi-randomly distributed in the ferroelectric P(VDF-TrFE) matrix. Magnetic properties have been investigated. The anisotropic nature of the Ni NWs had been highlighted by the highest coercivity and squareness in the parallel direction. The interaction between Ni NWs had also been evidenced by the improvement of the magnetic properties in the composite (a coercivity of 250 Oe and a squareness of 0.65 in the parallel direction). HRTEM images combined with SAED mode showed the monocrystallinity nature of the particles which allowed improving their magnetic properties. The P(VDF-TrFE)/Ni NW 0.3 vol% composite had been polarized under an electric field of 60 kV mm^{-1} and obtained a significant piezoelectric coefficient in the direction 3 of 7 pC N^{-1} . By associating the Ni NWs magnetism and the P(VDF-TrFE) piezoelectricity, a multiferroic composite with a very high magneto-electric coefficient was obtained. The

magneto-electric coefficient reached the value of 237 V/(m Oe) which is the highest found in the literature for composites with a polymer matrix.
