# HaEfliger structures and symplectic/Contact structures 

François Laudenbach \& GaËl Meigniez

#### Abstract

For some geometries including symplectic and contact structures on an $n$-dimensional manifold, we introduce a two-step approach to Gromov's $h$-principle. From formal geometric data, the first step builds a transversely geometric Haefliger structure of codimension $n$. This step works on all manifolds, even closed. The second step, which works only on open manifolds and for all geometries, regularizes the intermediate Haefliger structure and produces a genuine geometric structure. Both steps admit relative parametric versions. The proofs borrow ideas from W. Thurston, like jiggling and inflation. Actually, we are using a more primitive jiggling due to R. Thom.

## 1. Introduction

We consider geometric structures on manifolds, such as the following: symplectic structure, contact structure, foliation of prescribed codimension, immersion or submersion to another manifold. We recall that, in order to provide a given manifold $M$ with such a structure, Gromov's $h$-principle consists of starting from a formal version of the structure on $M$ (this means a non-holonomic - that is, non-integrable - section of some jet space) and deforming it until it becomes genuine (holonomic) [10]. In the present paper, we introduce a two-step approach to the $h$-principle for such structures.

From the formal data, the first step builds a Haefliger structure of codimension zero on $M$, transversely geometric; this concept will be explained below. For each of the geometries above-mentioned, the first step works for every manifold $M$, even closed.

The second step, which is works for open manifolds only, regularizes the intermediate Haefliger structure, providing a genuine geometric structure. Both steps admit relative parametric versions.

An essential tool in both steps consists of jiggling. We recall that Thurston's work on foliations used his famous Jiggling Lemma [19]. As A. Haefliger told us [9], Thurston himself was aware that this lemma applies for getting some $h$-principles in the sense of Gromov. In a not very popular paper by $R$. Thom [18], we discovered a more primitive jiggling lemma that is remarkably suitable for the needs of our approach.

[^0]1.1. Groupoids and geometries. According to O. Veblen and J.H.C. Whitehead [20], a geometry in dimension $n$ is defined by an $n$-dimensional model manifold $X$ (often $\mathbb{R}^{n}$ ) and by an open subgroupoid $\Gamma$ in the groupoid $\Gamma(X)$ of the germs of local $C^{\infty}$-diffeomorphisms of $X$; here the topology on $\Gamma(X)$ is meant to be the sheaf topology. In what follows, we use the classical notation $\Gamma_{n}:=\Gamma\left(\mathbb{R}^{n}\right)$. Here are examples of such open subgroupoids.
(1) When $n$ is even, $\Gamma_{n}^{\text {symp }} \subset \Gamma_{n}$ denotes the subgroupoid of germs preserving the standard symplectic form of $\mathbb{R}^{n}$.
(2) When $n$ is odd, $\Gamma_{n}^{\mathrm{cont}} \subset \Gamma_{n}$ denotes the subgroupoid of germs preserving the standard (positive) contact structure of $\mathbb{R}^{n}$.
(3) For $n=p+q$, one has the subgroupoid $\Gamma_{n, q}^{\mathrm{fol}} \subset \Gamma_{n}$ preserving the standard foliation of codimension $q$ (whose leaves are the $p$-planes parallel to $\mathbb{R}^{p}$ ).
(4) When $Y$ is any $q$-dimensional manifold and $X=\mathbb{R}^{p} \times Y$, one has the subgroupoid $\Gamma_{n}^{Y} \subset \Gamma(X)$ of the germs of the form $(x, y) \mapsto(f(x, y), y)$.
1.2. $\Gamma$-foliations. The next concept goes back to $A$. Haefliger [8]. For an open subgroupoid $\Gamma$ of $\Gamma(X)$, a $\Gamma$-foliation on a manifold $E$ is meant to be a codimension- $n$ foliation on $E$ equipped with a transverse geometry associated with $\Gamma$ and invariant by holonomy. More precisely, this foliation is defined by a maximal atlas of submersions $\left(f_{i}: U_{i} \rightarrow X\right)$ from open subsets of $E$ into $X$ such that, for every $i, j$ and every $x \in U_{i} \cap U_{j}$, there is a germ $\gamma_{i j} \in \Gamma$ at point $f_{j}(x)$ verifying
$$
\left[f_{i}\right]_{x}=\gamma_{i j}\left[f_{j}\right]_{x}
$$
where $[-]_{x}$ stands for the germ at $x$. When $n=\operatorname{dim} E$, one also speaks of a $\Gamma$-geometry on $E$.
Here are examples related to the previous list of groupoids. The first two have been already considered by D. McDuff in [13].
 of codimension $n$ at every point. The closedness of $\Omega$ is equivalent to the conjunction of the next facts:

- the codimension- $n$ plane field $\left(x \in E \mapsto \operatorname{ker} \Omega_{x}\right)$ is integrable,
- $\Omega$ is basic ${ }^{1}$ with respect to that foliation,
- $\Omega$ is closed on a total transversal.
(2) A $\Gamma_{n}^{\text {cont }}$-foliation on $E$ amounts to a codimension-one plane field $P$ on $E$ defined by an equation $A=0$ where $A$ is a differential form of degree 1 , unique up to multiplying by a positive ${ }^{2}$ function, which satisfies the next conditions:
- the $n$-form $A \wedge(d A)^{(n-1) / 2}$ is closed and has a codimension- $n$ kernel $K_{x}$ at every point $x \in E$; in particular, the field $\left(x \mapsto K_{x}\right)$ is integrable, tangent to a codimension- $n$ foliation denoted by $\mathcal{K}$;
- $K_{x}$ is a vector sub-space of $P_{x}$ for every $x$;
- $P$ is invariant by the holonomy of $\mathcal{K}$.
(3) A $\Gamma_{n, q}^{\mathrm{fol}}$-foliation on $E$ consists of a flag $\mathcal{F} \subset \mathcal{G}$ of two nested foliations of respective codimensions $n$ and $q$ in $E$ with $n>q$.

[^1](4) A $\Gamma_{n}^{Y}$-foliation on $E$ consists of a codimension- $n$ foliation and a submersion $w: E \rightarrow Y$ which is constant on every leaf ([8] p. 145).
1.3. Haefliger's $\Gamma$-structures. A. Haefliger defined a $\Gamma$-structure as some class of cocycles valued in $\Gamma$ (see [8] p. 137). This definition, that makes sense on every topological space and for every topological groupoid $\Gamma$, allowed him to build a classifying space $B \Gamma$ for these structures ([8] p. 140). A second description ([7] p. 188) is more suitable for our purpose when the topological space is a manifold $M$ and when the groupoid is an open subgroupoid $\Gamma$ in the groupoid of germs $\Gamma(X)$ of a $n$-manifold $X$. Here it is.

## $A \Gamma$-structure on $M$ consists of a pair $\xi=(\nu, \mathcal{F})$ where

- $\nu$ is a real vector bundle over $M$ of rank $n$, called the normal bundle; its total space is denoted by $E(\nu)$; and $Z: M \rightarrow E(\nu)$ denotes the zero section;
- $\mathcal{F}$ is a germ along $Z(M)$ of $\Gamma$-foliation in $E(\nu)$ transverse to every fibre of $\nu$.

An important feature of $\Gamma$-structures is that pulling back by smooth maps (in our restricted setting) is allowed without assuming any transversality: if $f: N \rightarrow M$ is a smooth map and $\xi$ is a $\Gamma$-structure on $M$, one defines $f^{*} \xi$ as the $\Gamma$-structure on $N$ whose normal bundle is $f^{*} \nu$ equipped with the $\Gamma$-foliation $F^{-1}(\mathcal{F})$, where $F$ is a bundle morphism over $f$ which is a fibre-to-fibre linear isomorphism.

Let $H^{1}(M ; \Gamma)\left(\right.$ resp. $\left.H_{\nu}^{1}(M ; \Gamma)\right)$ denote the space of the $\Gamma$-structures on $M$ (resp. those whose normal bundle is $\nu$ ). It is a topological space since $\Gamma$ is a topological groupoid; their elements are denoted by $\xi=(\nu, \mathcal{F})$. In what follows, we are mainly interested in the case where $\operatorname{dim} M=n$ and $\nu$ is isomorphic to the tangent space $\tau M$; in that case, the elements are just denoted $\mathcal{F}$.

In what follows, a $\Gamma$-structure on $M$ whose normal bundle is the tangent bundle $\tau M$ will be called a tangential $\Gamma$-structure. For short, when it is not ambiguous, we write $\mathcal{F}$ for $(\tau M, \mathcal{F})$. We introduced the general definition of $\Gamma$-structure - at least in the smooth case - since we are going to refer to in several places.
1.4. Underlying formal geometries. In the cases of the geometries (1), (2) and (4) given above, that is, for $\Gamma=\Gamma_{n}^{\text {symp }}, \Gamma_{n}^{\text {cont }}$ or $\Gamma_{n}^{Y}$, every $\Gamma$-structure has an underlying formal $\Gamma$ geometry in the sense of Gromov. But, we do not intend to enter Gromov's generality. We just describe what they are. In the case of the geometry (3), every $\Gamma_{n, q}^{\mathrm{fol}}$-structure has an underlying object, somewhat formal, but more complicated than in the cases (1), (2), (4).
(1) Assume $n$ is even. Given $\mathcal{F} \in H_{\tau M}^{1}\left(M ; \Gamma_{n}^{\text {symp }}\right)$, one has an associated basic closed 2form $\Omega$ on a neighborhood of $Z(M)$ in the total space $T M$. Its kernel is everywhere transverse to the fibres. Therefore, $\Omega$ defines a non-singular 2 -form $\omega$ on $M$ by the formula $\omega_{x}:=\Omega_{Z(x)} \mid T_{x} M$ for every $x \in M$. This is the underlying formal symplectic structure.
(2) Assume $n$ is odd. Given $\mathcal{F} \in H_{\tau M}^{1}\left(M ; \Gamma_{n}^{\text {cont }}\right)$, one has a $(n-1)$-plane field $Q$ defined near $Z(M)$ with the following properties:

- at each point $z$ near $Z(M)$, the plane $Q_{z}$ is vertical, meaning that it is contained in the fibre of $T M$ passing through $z$;
- $Q_{z}$ carries a symplectic bilinear form, well defined up to a positive factor;
- as a (conformally) symplectic bundle over a neighborhood of $Z(M)$, the plane field $Q$ is invariant by the holonomy of $\mathcal{F}$.
Then, there is a symplectic sub-bundle whose fibre at $x \in M$ is $S_{x}:=Q_{Z(x)}$ (the indeterminancy by a positive factor is irrelevant here). This is the underlying formal contact structure. Another way to say the same thing consists of the following: $S$ is the kernel of a 1 -form $\alpha$ and there is a 2 -form $\beta$ on $M$ such that $\beta$ makes $S$ be a symplectic bundle; equivalently, it may be said that $\alpha \wedge \beta^{\frac{n-1}{2}}$ is a volume form.
(3) Assume $n=p+q$. Given $\mathcal{F} \in H_{\tau M}^{1}\left(M ; \Gamma_{n, q}^{\text {fol }}\right)$, one has an associated foliation $\mathcal{G}$ of codimension $q$ on a neighborhood of $Z(M)$ in the total space $T M$. The foliation $\mathcal{G}$ induces on $M$ a $\Gamma_{q}$-structure $\gamma:=Z^{*}(\mathcal{G})$, whose normal bundle is $\nu_{\gamma}:=Z^{*}\left(\nu_{\mathcal{G}}\right)$; and a monomorphism of vector bundles $\epsilon: \nu_{\gamma} \hookrightarrow \tau M$. Indeed, for every point $x \in M$, the foliation $\mathcal{G}$ being transverse to $T_{x} M$ at $Z(x)$, the normal to $\mathcal{G}$ at $Z(x)$ embeds into $T_{x} M$. The pair $(\gamma, \epsilon)$, an augmented $\Gamma_{q}$-structure (according to the vocabulary from [4]), plays the role of a formal geometry associated to $\mathcal{F}$.
(4) Assume $n \geq \operatorname{dim} Y$. Given $\mathcal{F} \in H_{\tau M}^{1}\left(M, \Gamma_{n}^{Y}\right)$, one has an associated submersion $w$ from a neighborhood of $Z(M)$ in the total space $T M$ to $Y$. This submersion $w$ induces a formal submersion $(f, F)$ from $M$ to $Y$, that is, a bundle epimorphism from $T M$ to $T Y$ whose value at every $x \in M$ is: $f(x)=w(Z(x)), F_{x}:=D w_{Z(x)} \mid T_{x} M$.
Observe that all these spaces of formal geometries have natural topologies. Our first theorem yields a converse: for the above geometries, formal $\Gamma$-geometries lead to $\Gamma$-structures.

Theorem 1.5. Let $M$ be an n-dimensional manifold, possibly closed. Let $\Gamma$ be a groupoid in the set of $n$-dimensional geometries $\left\{\Gamma_{n}^{\text {symp }}, \Gamma_{n}^{\mathrm{cont}}, \Gamma_{n, q}^{\mathrm{fol}}, \Gamma_{n}^{Y}\right\}$. Then, the forgetful map from $H_{\tau M}^{1}(M ; \Gamma)$ to the corresponding space of formal $\Gamma$-geometries is a homotopy equivalence.

Remarks 1.6. 1) Actually, according to R. Palais ([16] Theorem 15), the considered spaces have the property that a weak homotopy equivalence is a genuine homotopy equivalence. Thus, it is sufficient to prove that the mentioned forgetful map is a weak homotopy equivalence, meaning that it induces an isomorphism of homotopy groups in each degree.
2) In the case of symplectic/contact geometry, D. McDuff proved theorems of the same flavor using the convex integration technique of Gromov ([13], see also [5] p. 104, 138).
3) Let $\mathcal{F} \in H_{\tau M}^{1}(M ; \Gamma)$. By taking a section $s$ of $\tau M$ valued in the domain foliated by $\mathcal{F}$ and generic with respect to $\mathcal{F}$, there is an induced $\Gamma$-geometry with singularities on $M \cong s(M)$. This seems to be a very natural notion of singular symplectic/contact structure. It follows from Theorem 1.9 that the singular locus may be localized in a ball of $M$.
1.7. Homotopy and regularization. Our second theorem will allow us to regularize every parametric family of $\Gamma$-structures on every manifold $M$ which is open, that is, which has no closed connected component; this terminology will be permanently used in what follows.
A homotopy (also called a concordance ${ }^{3}$ ) between two $\Gamma$-structures $\left(\nu_{i}, \mathcal{F}_{i}\right)(i=0,1)$ on $M$ is a $\Gamma$-structure on $M \times[0,1]$ whose restriction to $M \times 0$ (resp. $M \times 1$ ) equals ( $\nu_{0}, \mathcal{F}_{0}$ ) (resp. $\left.\left(\nu_{1}, \mathcal{F}_{1}\right)\right)$. Of course, $\nu_{0}$ and $\nu_{1}$ must be isomorphic.

A $\Gamma$-structure $(\nu, \mathcal{F})$ is said to be regular if the foliation $\mathcal{F}$ is transverse not only to the fibres of $\nu$ but also to $Z(M)$ in $E(\nu)$. This bi-transversality of $\mathcal{F}$ induces an isomorphism

[^2]$\nu \cong \tau(Z(M))$. In that case, the pull-back $Z^{*}(\mathcal{F})$ is a $\Gamma$-geometry on $M$, namely the foliation by points equipped with a transverse $\Gamma$-geometry.
1.8. The exponential $\Gamma_{n}$-structure. Given a complete Riemannian metric on the $n$-manifold $M$, there is a well defined map
$$
\exp : T M \rightarrow M .
$$

When restricting exp to a small neighborhood $U$ of $Z(M)$ in $T M$, we get a submersion to $M$. The foliation defined by the level sets of $\exp \mid U$ represents a regular $\Gamma_{n}$-structure on $M$, denoted by $\mathcal{F}_{\text {exp }} \in H_{\tau M}^{1}\left(M ; \Gamma_{n}\right)$. Up to isomorphism (vertical isotopy in $\left.T M\right), \mathcal{F}_{\text {exp }}$ does not depend on the Riemannian metric as it is shown by the next construction.

Consider the product $M \times M$ and its diagonal $\Delta \cong M$. We have two projections $p_{v}, p_{h}$ : $M \times M \rightarrow \Delta$, respectively the vertical and the horizontal projection. A small tube $U$ about $\Delta$ equipped with $p_{v}$ is isomorphic to $\tau M$ as micro-bundle. Then, the same tube equipped with $p_{h}$ defines the $\Gamma_{n}$-structure $\mathcal{F}_{\text {exp }}$.

We recall the fundamental property of the differential of $\exp$ (independent of any Riemannian metric):

$$
d\left(\exp \mid T_{x} M\right)_{Z(x)}=I d: T_{x} M \rightarrow T_{x} M
$$

As a consequence, if $f: M \rightarrow Y$ is a smooth map and $v \in T_{x} M$, one has

$$
\begin{equation*}
f \circ \exp _{x}(v)-f(x)=d f_{x}(v)+o(\|v\|) . \tag{1.1}
\end{equation*}
$$

Theorem 1.9. Let $X$ be an n-manifold, let $\Gamma \subset \Gamma(X)$ be an open subgroupoid and let $M$ be $a$ (connected) n-manifold. Assume that $M$ is open (that is, no connected component is closed). Let

$$
s \mapsto \xi_{s}=\left(\tau M, \mathcal{F}_{s}\right): \mathbb{D}^{k} \rightarrow H_{\tau M}^{1}(M ; \Gamma)
$$

be a continuous family of tangential $\Gamma$-structures, parametrized by the compact $k$-disk ( $k \geq 0$ ), such that for every $s \in \partial \mathbb{D}^{k}$, the $\Gamma$-structure $\xi_{s}$ is regular and $\mathcal{F}_{s}$ is tangent to $\mathcal{F}_{\text {exp }}$ along $Z(M)$.

Then, there exists a continuous family of concordances

$$
s \mapsto \bar{\xi}_{s}=\left(\tau M \times[0,1], \overline{\mathcal{F}}_{s}\right): \mathbb{D}^{k} \rightarrow H_{\tau M}^{1}(M \times[0,1] ; \Gamma)
$$

such that

- $\overline{\mathcal{F}}_{s}=p r_{1}^{*}\left(\mathcal{F}_{s}\right)$ for every $s \in \partial \mathbb{D}^{k}$, where $p r_{1}: M \times[0,1] \rightarrow M$ is the projection;
- $\overline{\mathcal{F}}_{s} \mid(M \times 0)=\mathcal{F}_{s}$ for every $s \in \mathbb{D}^{k}$;
- for every $s \in \mathbb{D}^{k}$, the $\Gamma$-structure $\bar{\xi}_{s} \mid(M \times 1)$ is regular and $\overline{\mathcal{F}}_{s}$ is tangent to $\mathcal{F}_{\text {exp }}$ along $Z(M \times 1)$.
Remark 1.10. The Smale-Hirsch classification of immersions $S \rightarrow Y$ (see [17, 12]), where $S$ is a closed manifold of dimension less than $\operatorname{dim} Y$, is covered by Theorem 1.9; in particular, the famous sphere eversion amounts to the case where $S$ is the 2 -sphere, $Y=\mathbb{R}^{3}$ and $k=1$. Let us show it.

Let $(f, F): T S \rightarrow T Y$ be a formal immersion. Then thanks to $F$ we have a monomorphism $F_{*}: \tau S \rightarrow f^{*} \tau Y$ over $I d_{S}$. Let $\nu$ be a complementary sub-bundle to the image of $F_{*}$; when $f$ is an immersion, $\nu$ is its normal bundle. Let $\hat{S}$ be a disk bundle in $\nu$; it is a compact manifold with non-empty boundary and $\operatorname{dim} \hat{S}=\operatorname{dim} Y$. Thus, instead of immersing $S$ to $Y$ one tries to immerse $\hat{S}$ to $Y$; if it is done, the restriction to the 0 -section yields an immersion of $S$ to $Y$ with normal bundle $\nu$. The formal immersion $(f, F): T S \rightarrow T Y$ easily extends to a formal
immersion $(\hat{f}, \hat{F}): \hat{S} \rightarrow Y$ in codimension 0 . Since $\hat{F}: T_{x} \hat{S} \rightarrow T_{\hat{f}(x)} Y$ is a linear isomorphism for every $x \in \hat{S}$, the level sets of $\exp _{Y} \circ F$ is a $\Gamma_{n}^{Y}$-foliation $\mathcal{F}$ near $Z(\hat{S})$, that is, a $\Gamma_{n}^{Y}$-structure on $\hat{S}$. Moreover, thanks to Equation (1.1), if $\hat{f}$ is an immersion $\mathcal{F}$ is tangent to $\mathcal{F}_{\text {exp }}$; here $\exp$ stands for $\exp _{\hat{S}}$. Then, Theorem 1.9 applies and yields the desired immersion (or family of immersions).

Corollary 1.11. Let $\Gamma$ be a groupoid as in Theorem 1.9 and $\xi=(\tau M, \mathcal{F})$ be a tangential $\Gamma$-structure on a closed manifold $M$. Then, after a suitable concordance, all singularities (that is, the points where $\mathcal{F}$ is not transverse to $Z(M) \cong M)$ are confined in a ball.
Proof. Let $B \subset M$ be a closed $n$-ball. Apply Theorem 1.9 to $\xi \mid(M \backslash$ int $B)$. We are given a regularization concordance $C$ of this restricted $\Gamma$-structure. Since this concordance is given on a manifold with boundary, it extends to the whole manifold. Indeed, $B \times[0,1]$ collapses to $(B \times\{0\}) \cup(\partial B \times[0,1])$.

Remark 1.12. Y. Eliashberg \& E. Murphy ([6] Corollary 1.6) gave a similar result for symplectic structures on closed almost symplectic manifolds of dimension greater than 4. Moreover, in the confining ball $B$ their singular symplectic structure is the negative cone of an overtwisted contact structure on $\partial B$. Their proof is based on the new techniques in contact geometry initiated by E. Murphy [15] and developped in [1].
1.13. The classical $h$-principle for $\Gamma$-geometries. For a groupoid $\Gamma$ as listed in 1.1 the $h$-principle states the following:

If $M$ is an open n-manifold, the space of $\Gamma$-geometries on $M$ has the same (weak) homotopy type as the space of formal $\Gamma$-geometries on $M$.

This statement follows from Theorems 1.5 and 1.9.
Proof. We start with a $k$-parameter family of formal $\Gamma$-geometries on $M, k \geq 0$, which are genuine $\Gamma$-geometries when the parameter $s$ lies in $\partial \mathbb{D}^{k}$. Then, for every $s \in \mathbb{D}^{\bar{k}}$, the foliation $\mathcal{F}_{\text {exp }}$ is a $\Gamma$-foliation near $Z(M)$. Thus, Theorem 1.5 applies and yields a $k$-parameter family of $\Gamma$-structures on $M$ which remains unchanged when $s \in \partial \mathbb{D}^{k}$. Now, since $M$ is open, Theorem 1.9 applies and all the relative homotopy groups of the pair (formal $\Gamma$-geometries, $\Gamma$-geometries) vanish.

The article is organized as follows. In Section 2, we detail the tool that goes back to R. Thom [18] and we prove Theorem 1.5 for submersion structures and for foliation structures. The next sections are devoted to the proof of Theorem 1.5 in the case of transversely symplectic structures. The existence part is treated in Section 3. The family of such structures are considered in Section 4; the proof of Theorem 1.5 is completed there when the groupoid is $\Gamma_{n}^{\text {symp }}$. In Section 5, we adapt the proof to the groupoid $\Gamma_{n}^{\text {cont }}$. Finally, in Section 6, we solve the problem of regularizing the $\Gamma$-structures on every open manifold.

## 2. Thom's subdivision and Jiggling

Reference [18] is the report of a lecture where R . Thom announced a sort of homological $h$ principle (ten years before Gromov's thesis). A statement and a sketch of proof are given there;
the details never appeared. From this text, we extracted an unusual subdivision process of the standard simplex and we derived two jiggling formulas ${ }^{4}$. Our jiggling will be vertical while Thom's jiggling is transverse to the fibres in some jet bundle. Nevertheless, we whall speak of Thom's jiggling for it mainly relies on Thom's subdivision. Actually, neither statement nor proof nor formula were written in [18], only words describing the object, a beautiful object indeed.

Here is a good occasion for mentioning that the famous Holonomic Approximation Theorem by Y. Eliashberg and N. Mishachev ([5] Chapter 3) is also based on a jiggling process, even if that word is not used there. The difference between their jiggling and ours is that the first one takes place in the manifold itself while the second one is somehow vertical in the total space of a fibre bundle.
Proposition 2.1. Let $\Delta^{n}$ denote the standard $n$-simplex. For every positive integer $n$, there exist a non-trivial subdivision $K_{n}$ of $\Delta^{n}$ and a simplicial map $\sigma_{n}: K_{n} \rightarrow \Delta^{n}$ such that:

1) (non-degeneracy) the restriction of $\sigma_{n}$ to any $n$-simplex of $K_{n}$ is surjective;
2) (heredity) for any $(n-1)$-face $F$ of $\Delta^{n}$, the intersection $K_{n} \cap F$ is simplicially isomorphic to $K_{n-1}$ and $\sigma_{n} \mid F \cong \sigma_{n-1}$.
Proof. Condition 2) implies $\sigma_{n}(v)=v$ for any vertex of $\Delta_{n}$. For $K_{1}$, we may take $\Delta^{1}=[0,1]$ subdivised by two interior vertices: $0<v_{1}<v_{0}<1$ and we define $\sigma_{1}$ by $\sigma_{1}\left(v_{1}\right)=1$ and $\sigma_{1}\left(v_{0}\right)=0$.

For $n=2$, let $A, B, C$ denote the vertices of $\Delta^{2}$. The polyhedron $K_{2}$ will be built in the following way: subdivide each edge of $\Delta_{2}$ as $K_{1}$ subdivides $\Delta_{1}$; add an interior triangle with vertices $a, b, c$ so that the line supporting $[b, c]$ is parallel to $[B, C]$ and separates $A$ from $a$, etc.; join $a$ to the four vertices of $[B, C]$, etc. The simplicial map $\sigma_{2}$ is defined by $a \mapsto A, b \mapsto B, c \mapsto$ $C$ and by imposing to coincide with $\sigma_{1}$ on each edge of $\Delta^{2}$. Condition 1) is easily checked.

This construction extends to any dimension. If $K_{n-1}$ and $\sigma_{n-1}$ are known, each facet of $\Delta^{n}$ will be sudivided as $K_{n-1}$. Then, one puts a small $n$-simplex $\delta^{n}$ in the interior of $\Delta^{n}$ applying the same rules of parallelism and separation as for $n=2$. Each vertex $v$ of $\delta^{n}$ will be joined to the vertices of the facet $F(v)$ of $\Delta^{n}$ in front of $v$, this facet being sudivided by $K_{n-1}$. The map $\sigma_{n}$ maps $v$ to the vertex $V$ which is opposite to $F(v)$ in $\Delta^{n}$.

Remarks 2.2.1) This subdivision may be iterated $r$ times producing a subdivision $K_{n}^{r}$ which is arbitrarily fine and a simplicial map $\sigma_{n}^{r}: K_{n}^{r} \rightarrow \Delta^{n}$ fulfilling the two conditions of Proposition 2.1. More precisely, thinking of $\sigma_{n}$ as a map from $\Delta^{n}$ to itself, $\sigma_{n}^{r}$ will denote its $r$-th iterate and $K_{n}^{r}$ is defined by the next formula:

$$
\begin{equation*}
K_{n}^{r}=\left(\sigma_{n}^{r-1}\right)^{-1}\left(K_{n}\right) \tag{2.1}
\end{equation*}
$$

We will call $\sigma_{n}^{r}$ an $r$-folding map.
2) Thanks to heredity (condition that the barycentric subdivision does not fulfil), this subdivision of the standard simplex and the $r$-folding map apply to any polyhedron.
3) It is worth noticing that Thom's subdivision is not crystalline in the sense of H. Whitney ([21] Appencice II). Thus, it does not fit Thurston's techniques of jiggling (compare [19]).

[^3]Actually, the above construction has an unfolding property which is stated in the next proposition.

Proposition 2.3. With the above notations, for every $n$-simplex $\tau$ of $K_{n}^{r-1}$, the restriction $\sigma_{n}^{r} \mid \tau$ is homotopic to $\sigma_{n}^{r-1} \mid \tau$ among piecewise linear maps $\tau \rightarrow \Delta^{n}$ which are compatible with the face operators.

Proof. According to formula (2.1) it is sufficient to prove the proposition for $\sigma_{n} \equiv \sigma_{n}^{1}$. In that case, $\sigma_{n}^{r-1}=I d$. The homotopy is obvious for $n=1$; it consists of shrinking the middle interval $\delta^{1}$ to the barycenter of $\Delta^{1}$ and shrinking its image at the same time. Recursively, the homotopy of $\sigma_{n}$ is known on the faces of $\Delta^{n}$. Then, it is sufficient to define the homotopy on the interior small $n$-simplex $\delta^{n}$. As when $n=1$, the homotopy consists of shrinking $\delta^{n}$ and its image simultaneously to the barycenter of $\Delta^{n}$.
2.4. First jiggling formula. Let $M$ be an $n$-manifold and $\tau M=(T M \xrightarrow{p} M)$ be its tangent bundle. Choose an auxiliary Riemannian metric on $\tau M$ and an arbitrarily small open disk sub-bundle $U$ so that, for every $x \in M$, the exponential map $\exp _{x}: U_{x} \rightarrow M$ is an embedding. Take a combinatorial triangulation $T$ of $M$ so fine that every $n$-simplex $\tau$ of $T$ is covered by $\exp _{x}\left(U_{x}\right)$ for every $x \in \tau$. Let $T^{r}$ be the $r$-th Thom subdivision of $T$ and $\sigma^{r}: T^{r} \rightarrow T$ be the corresponding simplicial folding map. The $r$-th jiggling map $j^{r}: M \rightarrow T M$ is defined in the following way. For each $x \in M$, the point $j^{r}(x)$ is the unique point in $U_{x}$ such that

$$
\begin{equation*}
\exp _{x}\left(j^{r}(x)\right)=\sigma^{r}(x) \tag{2.2}
\end{equation*}
$$

This formula defines $j^{r}$ as a piecewise smooth section $M \rightarrow T M$. We have the following properties.
Proposition 2.5. 1) Let $\tau$ be an n-simplex of $T$, let $x$ be a point in $\tau$ and let $\delta$ be an n-simplex of $T^{r}$ passing through $x$. Then, $j^{r}(\delta)$ goes to $\exp _{x}^{-1}(\tau)$ as $r \rightarrow \infty$. The convergence is uniform for $x \in \tau$.
2) The map $j^{r}$ is homotopic to the 0-section $Z$ among PL maps which are transverse to the exponential foliation $\mathcal{F}_{\text {exp }}$ on each $n$-simplex of their domain.

Proof. 1) The diameter of the simplices of $T^{r}$ goes to 0 as $r$ goes to $\infty$. Then, for $y \in \delta$, the point $j^{r}(y):=\exp _{y}^{-1}\left(\sigma^{r}(y)\right)$ is close to $\exp _{x}^{-1}\left(\sigma^{r}(y)\right)$. Since $\sigma^{r}$ is a surjective simplicial map onto $\tau$, we have the $C^{0}$ closeness of $j^{r}(\delta)$ and $\exp _{x}^{-1}(\tau)$. A similar argument holds for the derivatives.
2) On the one hand, the leaves of $\mathcal{F}_{\text {exp }}$ in $U$ are $n$-disKs. We define $\exp ^{u}: U \rightarrow U, u \in[0,1]$, to be the map which is the homothety by $u$ in each fibre of $\exp$. It is a homotopy from $I d_{U}$ to $\exp \mid U$ which restricts to a homotopy from $j^{r}$ to $\sigma^{r}$. On the other hand, according to Proposition 2.3, $\sigma^{r}$ is homotopic to $I d_{M}$ through $P L$ maps which are non-degenerate on each $n$-simplex of their domain, hence transverse to $\mathcal{F}_{\text {exp }}$.

## Remarks 2.6.

1) Any piecewise smooth map defined on an $n$-manifold $M$ and smooth on each $n$-simplex of a triangulation $T$ may be approximated by a smooth map with the same polyhedral image. It is sufficient to precompose with a smooth homeomorphism such that, for every simplex $\tau$ in the
( $n-1$ )-skeleton of $T$ and every $x \in \tau$, all partial derivatives in directions transverse $\tau$ vanish at $x$. Then, even if the concept of $\Gamma$-structure is restricted to the smooth category, there is no trouble to pull-back a $\Gamma$-structure by $j^{r}$; it will be well defined up to homotopy.
2) In general a jiggling, for instance based on the iterated barycentric triangulation, does not share the properties stated in Proposition 2.5 (non-degeneracy and PL-homotopy).
2.7. Second jiggling formula. Here, we consider a trivial bundle $\varepsilon^{n}$ of rank $n$ whose base is an $n$-manifold $M$ equipped with a colored triangulation ${ }^{5}$. Let $\Delta^{n} \subset \mathbb{R}^{n}$ be a non-degenerate $n$-simplex whose vertices are colored. The coloring defines a simplicial map $c: T \rightarrow \Delta^{n}$. We have a first jiggling $j^{1}: M \rightarrow M \times \mathbb{R}^{n}, x \mapsto(x, c(x))$. Then, the Thom process defines a $r$-th jiggling

$$
\begin{equation*}
j^{r}(x)=\left(x, c \circ \sigma^{r}(x)\right) . \tag{2.3}
\end{equation*}
$$

The first item of Proposition 2.5 holds true for this formula: $j^{r}(\delta)$ tends to $\{x\} \times \Delta^{n}$ when $n$ goes to $\infty$.
2.8. Proof of theorem 1.5 in the easy cases. For two of the four geometries considered, namely the submersion geometry $\Gamma_{n}^{Y}$ and the foliation geometry $\Gamma_{n, q}^{\text {fol }}$, the jiggling method yields directly a simple proof of theorem 1.5.
For the submersion geometry, we begin by proving that the forgetful map is $\pi_{0}$-surjective. One is given an $n$-manifold $M$, a $q$-manifold $Y$ and a formal submersion (in the sense of Subsection $1.4(4))$, that is, a pair $(f, F)$, where $f: M \rightarrow Y$ is a smooth map and where $F: T M \rightarrow T Y$ is a bundle epimorphism above $f$. One seeks for a one-parameter family ( $f_{u}, F_{u}$ ) of formal submersions, $u \in[0,1]$, such that $\left(f_{0}, F_{0}\right)=(f, F)$, and such that $\left(f_{1}, F_{1}\right)$ underlies some $\Gamma_{n}^{Y}$ structure $\xi=(\tau M, \mathcal{F})$. According the definitions given in Subsections 1.2 and 1.4, we have to find a pair $(w, \mathcal{F})$ formed with a submersion valued in $Y$ and a codimension- $n$ foliation, both defined near $Z(M)$ in $T M$, such that:

- $w$ is constant on each leaf of $\mathcal{F}$;
- $f_{1}(x)=w(Z(x))$ and $F_{1}=D w_{Z(x)} \mid T_{x} M$.

This will work by taking $w=\exp \circ F$ which is clearly a submersion on some neighborhood $U$ of $Z(M)$ in $T M$; here, $Y$ is endowed with some auxiliary Riemannian metric and exp :TY $\rightarrow Y$ is the associated exponential map. The only somehow delicate point is to find $\mathcal{F}$ as a subfoliation of the foliation $\mathcal{W}$ whose leaves are $w^{-1}(y), y \in Y$. Let $P$ be an $n$-dimensional plane field on $U$ transverse to every fibre $T_{x} M$ and contained in the kernel of the differential of $w$.

Let $T$ be a triangulation of $M$. Consider the iterated Thom subdivisions $T^{r}$. By Proposition 2.5 (1), for $r$ large enough, the $r$-th Thom jiggling $j^{r}$ maps every $n$-simplex of $T^{r}$ into $U$ and transversely to $P$. Fix such an $r$. Then, on some small open neighborhood $V$ of $j^{r}\left(T^{r}\right)$ in $T M$, there is a $C^{0}$-small perturbation of $P$, among the $n$-plane fields tangent to $\mathcal{W}$, yielding an integrable plane field on $V$. In the present situation where the dimension of the simplicial complex $j^{r}\left(T^{r}\right)$ is not larger than the codimension of $P$, the wanted integrating perturbation can be easily constructed by induction on the dimension of the simplices (see the very beginning of Section 6 in [19]).

[^4]Let $S: M \rightarrow T M$ be a smooth section so close to $j^{r}$, that $S(M) \subset V$. For every $u \in[0,1]$, one has the section $S_{u}:=u S$ valued in $U$. Set $f_{u}:=w \circ S_{u}$, and $F_{u}\left(v_{x}\right):=D w_{u S(x)} v_{x}$. The structure $S^{*}(w, \mathcal{F})$ is really a $\Gamma_{n}^{Y}$-structure whose underlying formal structure is $\left(f_{1}, F_{1}\right)$. The $\pi_{0}$-surjectivity is proved.

More generally, one is given a parametric family of formal submersions $\left(f_{s}, F_{s}\right), s \in \mathbb{D}^{k}$, which are underlying some $\Gamma_{n}^{Y}$-structures $\mathcal{F}_{s} \in H_{\tau M}^{1}\left(M ; \Gamma_{n}^{Y}\right)$ for every $s \in \partial \mathbb{D}^{k}$. First, one constructs, on some open neighborhood $U$ of the zero section in $T M$ and for every $s \in \mathbb{D}^{k}$, an $n$-plane field $P_{s}$ as above: $P_{s}$ is contained in $\operatorname{ker} D\left(\exp \circ F_{s}\right)$, and transverse to every fibre $T_{x} M$. One arranges that $P_{s}$ depends smoothly on $s$, and coincides with the tangent space to $\mathcal{F}_{s}$ for every $s \in \partial \mathbb{D}^{k}$. The construction of such a family is easy, by convexity ${ }^{6}$ of the space of the $n$-plane fields on $U$ contained in $\operatorname{ker}\left(D\left(\exp \circ F_{s}\right)\right)$ and transverse to the fibres.

Let $T$ be a triangulation of $M$, and let $T^{r}$ be a Thom subdivision whose order $r$ is large enough so that the same jiggling $j^{r}\left(T^{r}\right)$ is transverse to $P_{s}$ for every $s \in \mathbb{D}^{k}$; since the considered family is compact, such an $r$ certainly exists. Then, the integrating perturbation can be chosen smoothly with respect to $s$ and coinciding with the identity for every $s \in \partial \mathbb{D}^{k}$. A single neighborhood $V$ and a single section $S$ fit all parameters $s \in \mathbb{D}^{k}$. We get on $V$ a parametric family $\left(\mathcal{P}_{s}\right)$ of $\Gamma_{n}^{Y}$-foliations transverse to every fibre $T_{x} M$; and $\mathcal{P}_{s}=\mathcal{F}_{s} \mid V$ for every $s \in \partial \mathbb{D}^{k}$.

Define $S$ and $S_{u}$ as above. Set $\mathcal{F}_{s}:=S^{*}\left(\mathcal{P}_{s}\right) \in H_{\tau M}^{1}\left(M, \Gamma_{n}^{Y}\right)$. Set $f_{s, u}:=\exp \circ F_{s} \circ S_{u}$ and $F_{s, u}\left(v_{x}\right):=D\left(\exp \circ F_{s}\right)_{u S(x)} v_{x}$. This is a one-parameter family of $\mathbb{D}^{k}$-parametrized families of formal submersions, between $\left(f_{s, 0}, F_{s, 0}\right)=\left(f_{s}, F_{s}\right)$ and $\left(f_{s, 1}, F_{s, 1}\right)$, which is the formal submersion underlying $\mathcal{F}_{s}$.

Finally, the families $\left(\mathcal{F}_{s}\right)$ and $\left(\mathcal{F}_{s}\right) \mid \partial \mathbb{D}^{k}$ are homotopic as mappings $\partial \mathbb{D}^{k} \rightarrow H_{\tau M}^{1}\left(M, \Gamma_{n}^{Y}\right)$. The homotopy consists of pulling $\mathcal{F}_{s}$ back through $S_{u}$. The proof of Theorem 1.5 is complete for the groupoid $\Gamma_{n}^{Y}$.

In the case of the foliation geometry on a manifold $M$ of dimension $n=p+q$, we are given a parametric family of augmented $\Gamma_{q}$-structures $\left(\xi_{s}, \epsilon_{s}\right), s \in \mathbb{D}^{k}$. Moreover, for every $s \in \partial \mathbb{D}^{k}$, the augmented $\Gamma_{q}$-structure $\left(\xi_{s}, \epsilon_{s}\right)$ is underlying some $\Gamma_{n, q}^{\mathrm{fol}}$-structure $\mathcal{F}_{s} \in H_{\tau M}^{1}\left(M ; \Gamma_{n, q}^{\mathrm{fol}}\right)$.

Denote $\xi_{s}:=\left(\nu, \mathcal{X}_{s}\right)$ this family of $\Gamma_{q}$-structures. Of course, the normal vector bundle $\nu$ over $M$ does not depend on $s \in \mathbb{D}^{k}$. Recall that $\epsilon_{s}: \nu \hookrightarrow T M$ is a monomorphism of vector bundles.

For every $s \in \partial \mathbb{D}^{k}$, denote by $\mathcal{G}_{s}$ the foliation of codimension $q$ tangent to $\mathcal{F}_{s}$ on a neighborhood $U$ of $Z(M)$ in $T M$; that is, if $\mathcal{F}_{s}$ is viewed as a codimension- $n$ foliation, we have $\mathcal{F}_{s} \subset \mathcal{G}_{s}$. For every $x \in M$, define $\tau_{s}(x):=\left(T \mathcal{G}_{s}\right)_{Z(x)} \cap T_{x} M$ to be the $p$-plane tangent to the foliation $\mathcal{G}_{s} \cap T_{x} M$ at $Z(x)$. Thus, $\tau M=\tau_{s} \oplus \epsilon_{s}(\nu)$. The family $\left(\tau_{s}\right)$ extends to a $\mathbb{D}^{k}$-parametrized family ( $\tau_{s}$ ) of $p$-plane fields on $M$ complementary to $\epsilon_{s}(\nu)$.

For every $s \in \partial \mathbb{D}^{k}$, after pushing $\mathcal{G}_{s}$ by a vertical isotopy in $T M$, whose 1 -jet at every point of the zero section is the identity, and after restricting to some smaller neighborhood, one can moreover assume that the trace $\mathcal{G}_{s} \cap\left(T_{x} M \cap U\right)$ is the restriction to $T_{x} M \cap U$ of the linear $p$-dimensional foliation parallel to $\tau_{s}(x)$. Then, the family $\left(\mathcal{G}_{s}\right)$ extends to a $\mathbb{D}^{k}$-parametrized family $\left(\mathcal{G}_{s}\right)$ of foliations of codimension $q$, transverse to the fibres of $T M \rightarrow M$ and defined on some neighborhood $U$ of $Z(M)$ independent of $s$. Indeed, for every $s \in \mathbb{D}^{k} \backslash \partial \mathbb{D}^{k}$, we define $\mathcal{G}_{s}$ as the pullback of $\mathcal{X}_{s}$ through the linear projection of $T M=\tau_{s} \oplus \epsilon_{s}(\nu)$ onto $\epsilon_{s}(\nu)$ parallel to $\tau_{s}$.

[^5]Just as in the case of the submersion geometry, one constructs a $\mathbb{D}^{k}$-parametrized smooth family $\left(P_{s}\right)$ of $n$-plane fields on $U$, transverse to the fibres $T_{x} M$, and contained in $T \mathcal{G}_{s}$. For $s \in \partial \mathbb{D}^{k}$, one has $P_{s}=T \mathcal{F}_{s}$. For a large enough integer $r$, a $C^{0}$-small perturbation of $P_{s}$ yields a foliation $\mathcal{P}_{s}$ of codimension $n$, contained in $\mathcal{G}_{s}$, on some open neighborhood $V$ of the jiggled zero section $j^{r}\left(T^{r}\right)$. For $s \in \partial \mathbb{D}^{k}$, one has $\mathcal{P}_{s}=\mathcal{F}_{s}$.

Define sections $S, S_{u}$ as above. For every $s \in \mathbb{D}^{k}$, set $\mathcal{F}_{s}^{\prime}:=S^{*}\left(\mathcal{P}_{s}\right) \in H_{\tau M}^{1}\left(M, \Gamma_{n, q}^{\text {fol }}\right)$. The underlying augmented $\Gamma_{q}$-structure is homotopic to the given one ( $\xi_{s}, \epsilon_{s}$ ). The homotopy consists of the 1-parameter family of $\mathbb{D}^{k}$-parametrized families of augmented $\Gamma_{q}$-structures $\left(\nu, S_{u}^{*}\left(\mathcal{G}_{s}\right), \epsilon_{s}\right)$ (note that $\mathcal{G}_{s}$ is defined on the whole of the open set $U$ ). Finally, the $\partial \mathbb{D}^{k}$-parametrized families $\mathcal{F}_{s}$ and $\mathcal{F}_{s}^{\prime}$ of $\Gamma_{n, q}^{\mathrm{fol}}$-structures are homotopic: the homotopy consists of $\mathcal{F}_{s, u}:=S_{u}^{*}\left(\mathcal{F}_{s}\right)$. The proof of Theorem 1.5 is complete for the groupoid $\Gamma_{n, q}^{\text {fol }}$.

## 3. Existence of transversely symplectic $\Gamma_{n}$-Structures

In this section we prove a slightly more general statement than the existence part of Theorem 1.5 for the groupoid $\Gamma_{n}^{\text {symp }}$ : we consider any symplectic bundle of rank $n$. We are going to use a more informative notation: a $\Gamma_{n}^{\text {symp }}$-structure on $M$ will be denoted by $\xi=(\nu, \mathcal{F}, \Omega)$ where $\Omega$ is a closed 2-form whose kernel is $\mathcal{F}$.

Theorem 3.1. Let $\nu=(E \rightarrow M)$ be a symplectic bundle of even rank $n$ over a manifold $M$ of dimension $\leq n+1$. Then there exists a $\Gamma_{n}^{\text {symp }}$-structure $\xi$ on $M$ whose normal bundle $\nu(\xi)$ is isomorphic to $\nu$ as a symplectic bundle.

Moreover, if a real cohomology class $\bar{a} \in H^{2}(M, \mathbb{R})$ is given, $\xi$ can be chosen so that the cohomology class $\left[Z^{*} \Omega\right]$ equals $\bar{a}$, where $\Omega$ is the closed 2 -form underlying $\xi$.
We think of this problem as a lifting problem that we attack by obstruction theory. Let us explain how it works. As for any groupoid of germs, there are a classifying space ${ }^{7} B \Gamma_{n}^{\text {symp }}$ and a canonical isomorphism

$$
\Gamma_{n}^{\text {symp }}(M) \cong\left[M, B \Gamma_{n}^{\text {symp }}\right]
$$

where $[-,-]$ stands for the set of homotopy classes of maps.
This classifying space is the source of two maps. The first one is $\beta: B \Gamma_{n}^{\text {symp }} \rightarrow B S p(n ; \mathbb{R})$ : if $f: M \rightarrow B \Gamma_{n}^{\text {symp }}$ classifies a $\Gamma_{n}^{\text {symp }}$-structure $\xi=(\nu, \mathcal{F}, \Omega)$ up to concordance, $\beta \circ f$ classifies its normal bundle $\nu$. The second one is $\kappa: B \Gamma_{n}^{\text {symp }} \rightarrow K(\mathbb{R}, 2)$, where the target is the Eilenberg-MacLane space classifying the functor $H^{2}(-, \mathbb{R})$ : the composed map $\kappa \circ f$ classifies the cohomology class of the closed 2-form $Z^{*} \Omega$. Finally, the pair $(\beta, \kappa)$ defines a map

$$
\pi^{\text {symp }}: B \Gamma_{n}^{\text {symp }} \rightarrow B S p(n ; \mathbb{R}) \times K(\mathbb{R}, 2)
$$

that we see as a homotopy fibration. For Theorem 3.1, we are given a map $M \rightarrow B S p(n ; \mathbb{R}) \times$ $K(\mathbb{R}, 2)$ and we have to lift this map to $B \Gamma_{n}^{\text {symp }}$. Since $M$ is $(n+1)$-dimensional, Theorem 3.1 is a direct corollary of the next statement (the $(n-1)$-connectedness would be sufficient for Theorem 1.5). Indeed, thanks to the long exact sequence associated with $\pi^{\text {symp }}$, this map induces a monomorphism up to the $n$-th homotopy group (see, for instance Hatcher's book [11], Section 4.3).

[^6]Theorem 3.2. (Haefliger, McDuff) The homotopy fibre of $\pi^{\text {symp }}$, denoted by $F \pi^{\text {symp }}$, is $n$-connected.
A. Haefliger ([8], Section 6) showed that the $(n-1)$-connectedness of this homotopy fibre is a consequence of the $h$-principle. D. McDuff ([13], Theorem 6.1) proved the $n$-connectedness thanks to the convex integration technique.
3.3. What do we have to prove for Theorem 3.2? We have to prove that the $k$-th homotopy group $\pi_{k}\left(F \pi^{\text {symp }}\right)$ vanishes when $k \leq n$. An element of this group is represented by a $\Gamma_{n}^{\text {symp }}$-structure $\xi=\left(\varepsilon^{n}, \mathcal{F}, \Omega\right)$ on the $k$-sphere with the following properties:

- The normal bundle is trivial as a symplectic bundle; this means that its underlying symplectic bilinear form is the standard form $\omega_{0}$ of $\mathbb{R}^{n}$ on each fibre.
- The closed 2 -form $\Omega$, which is defined in a neighborhood of the 0 -section $Z\left(S^{k}\right)$ in $\mathbb{S}^{k} \times \mathbb{R}^{n}$, is assumed to be exact.
Let $\left(p_{1}, p_{2}\right)$ denote the two projections of $\mathbb{S}^{k} \times \mathbb{R}^{n}$ onto its factors. Recall that the kernel of $\Omega$ is the tangent space to the codimension- $n$ foliation $\mathcal{F}$ and that $\mathcal{F}$ is transverse to the fibres of $p_{1}$.

We have to extend this structure $\xi$ over the $(k+1)$-ball $\mathbb{D}^{k+1}$ or, equivalently, to show that it is homotopic to the trivial structure $\xi_{0}:=\left(\varepsilon^{n}, \mathcal{F}_{0}, \Omega_{0}\right)$ where $\Omega_{0}=p_{2}^{*} \omega_{0}$.

According to Moser's Lemma with $k$ parameters [14], there exists a vertical isotopy of $\mathbb{S}^{k} \times \mathbb{R}^{n}$, keeping $Z$ fixed, which reduces us to the case where the germ at $Z(x)$ of the form induced by $\Omega$ on $p_{1}^{-1}(x)$ equals $\omega_{0}$ for every $x \in \mathbb{S}^{k}$. After this vertical Moser isotopy, take a trivial tube $U=\mathbb{S}^{k} \times B^{n}$ in the domain of $\Omega$, where $B^{n}$ is an $n$-ball of small radius. Now, Theorem 3.2 directly follows from the next lemma, as we will see just after its statement.

Lemma 3.4. Given the above-mentioned data, there exist a section $s: \mathbb{S}^{k} \rightarrow U$, a neighborhood $W$ of $s\left(\mathbb{S}^{k}\right)$ in $U$ and an ambient diffeomorphism $\psi$ such that:
(1) $\psi$ is the time-1 map of a vertical isotopy $\left(\psi_{t}\right)$; set $W_{0}:=\psi(W)$;
(2) $\psi$ sends the pair $(W, \Omega)$ to $\left(W_{0}, \Omega_{0}\right)$;
(3) the isotopy $\psi_{t}$ is Hamiltonian with respect to $\omega_{0}$ in each fibre.

Here, "vertical" means that the isotopy preserves each fibre of $p_{1}$.

## Remarks 3.5.

1) The statement holds true for every symplectic vector bundle of rank $n$, equipped (near the 0 -section) with two forms exact forms $\Omega$ and $\Omega_{0}$ which define $\Gamma_{n}^{\text {symp }}$-foliations and induce the same symplectic form on each fibre.
2) Moreover, the two first items are valid for a pair of $\Gamma_{n}$-foliations without any transverse geometry.

Proof of Theorem 3.2. Since $\psi$ is vertical, $s_{0}:=\psi o s$ is a section of the trivial bundle $\varepsilon^{n}$ over $\mathbb{S}^{n}$. Also, recall the 0 -section $Z$. Then, we have a sequence of homotopies of $\Gamma_{n}^{\text {symp }}$-structures on $\mathbb{S}^{k}$ :

- a first homotopy from $Z^{*} \Omega$ to $s^{*} \Omega$;
- then, a homotopy from $s^{*} \Omega$ to $s_{0}^{*} \Omega_{0}$ defined by the isotopy $\left(\psi_{t}\right)$;
- a last homotopy from $s_{0}^{*} \Omega_{0}$ to $Z^{*} \Omega_{0}$.

The last structure obviously extends to the $(k+1)$-ball.
Shortly said, the proof of Lemma 3.4 will consist of taking a jiggled section in the sense of formula (2.3) whose simplices are very vertical, then covering it by boxes which trivialize the kernel of $\Omega$ and pushing these boxes by some vertical Hamiltonian isotopy until ker $\Omega$ becomes horirontal. This isotopy is done recursively on the boxes. There are two main problems:

- rectifying the $(j+1)$-th box should not destroy what was gained for the $j$-th box;
- manage the vertical isotopies to be Hamiltonian and not just symplectic; if not, they could not extend.

Proof of Lemma 3.4. We limit ourselves to $k=n$; for $k<n$, it is the same argument by replacing the base $\mathbb{S}^{k}$ with an $n$-dimensional base $\mathbb{S}^{k} \times \mathbb{D}^{n-k}$. Let $B^{n}:=p_{2}(U)$ and let $\Delta^{n}$ be a non-degenerate and colored $n$-simplex in the interior of $B^{n}$.

Take a decreasing sequence

$$
\varepsilon_{0}>\cdots>\varepsilon_{j}>\cdots>\varepsilon_{n-1} .
$$

When $\alpha$ is a strict closed $j$-face of $\Delta^{n}$, let $N(\alpha)$ denote the closed $\varepsilon_{j}$-neighborhood of $\alpha$ in $\mathbb{R}^{n}$. Set

$$
N\left(\Delta^{n}\right):=\Delta^{n} \cup \underset{\alpha}{\cup} N(\alpha)
$$

where the union is taken over all faces of $\Delta^{n}$. For a suitable choice of the sequence $\left(\varepsilon_{j}\right)$ we may arrange that :
(1) $N(\alpha) \cap N(\beta)=\emptyset$ if $\alpha$ and $\beta$ are two disjoint faces;
(2) if $\alpha \cap \beta \neq \emptyset$ and if $\alpha$ and $\beta$ are not nested, then $N(\alpha) \cap N(\beta)$ is interior to $N(\alpha \cap \beta)$;
(3) $N\left(\Delta^{n}\right) \subset B^{n}$.

Now, take a colored triangulation $T$ of the base $\mathbb{S}^{n}$, its Thom subdivision $T^{r}$ and the associated jiggling $j^{r}$ given by formula (2.3). We are going to construct bi-foliated boxes associated with each simplex of $T^{r}$ whose plaques are respectively contained in the leaves of $\mathcal{F}$ and in the fibres of $p_{1}$; the boundary of a box has a part tangent to $\mathcal{F}$ and another part tangent to the fibres. Let $\tau$ be a $k$-simplex of $T^{r}$; with $\tau$, the coloring of $T$ associates some face $\tau^{\perp}$ of $\Delta^{n} \subset B^{n}$. The box $B(\tau)$ is defined in the following way. Its base $p_{1}(B(\tau))$ equals $\operatorname{star}(\tau)$, the star of $\tau$ in $T^{r}$. In the fibre over the barycenter $b(\tau)$, we take the domain $N\left(\tau^{\perp}\right)$. Finally, $B(\tau)$ is the union of all plaques of $\mathcal{F}$ passing through $N\left(\tau^{\perp}\right)$ and contained in $p_{1}^{-1}(\operatorname{star}(\tau))$. If the diameter of the base is small enough, that is, if the order $r$ of the subdivision is large enough, the holonomy of $\mathcal{F}$ over the base is $C^{0}$ close to Identity. Therefore, each plaque in $B(\tau)$ cannot get out of $U$; thus, it covers $\operatorname{star}(\tau)$.

Look at two faces $\tau$ and $\tau^{\prime}$ of the same simplex $\sigma$ of $T^{r}$. Assume first that $\tau$ and $\tau^{\prime}$ are disjoint. Apply the above condition (1) to $\tau^{\perp}$ and $\tau^{\prime \perp}$; by the holonomy argument, if $r$ is large enough, the boxes $B(\tau)$ and $B\left(\tau^{\prime}\right)$ are disjoint. Assume now that $\tau$ and $\tau^{\prime}$ are not disjoint but not nested. Then, by (2), we have

$$
B(\tau) \cap B\left(\tau^{\prime}\right) \subset B\left(\tau \cap \tau^{\prime}\right)
$$

Nevertheless, if $\tau$ and $\tau^{\prime}$ do not belong to the same $n$-simplex and if $\partial \operatorname{star}(\tau) \cap \partial \operatorname{star}\left(\tau^{\prime}\right) \neq \emptyset$, then $B(\tau)$ and $B\left(\tau^{\prime}\right)$ could intersect badly. This is corrected in the following way.

Again, for $r$ large enough, the leaves of $\mathcal{F}$ meeting $j^{r}(\tau)$ intersect the fibre over $b(\tau)$ in $N\left(\tau^{\perp}\right)$. This guarantees that $j^{r}\left(T^{r}\right)$ is covered by the interior of the boxes. From now on, $r$ is fixed. For $1>\eta>0$, the $\eta$-reduced box associated with $\tau$ is defined by

$$
B_{\eta}(\tau):=B(\tau) \cap p_{1}^{-1}((1-\eta) \operatorname{star}(\tau))
$$

where the homothety is applied from the barycenter $b(\tau)$. Fix $\eta>0$ small enough so that the $\eta$-reduced open boxes still cover the jiggling. Now, we are sure that $B_{\eta}(\tau)$ and $B_{\eta}\left(\tau^{\prime}\right)$ are disjoint once $\tau$ and $\tau^{\prime}$ are disjoint.

The desired open set $W$ is the union $V_{0} \cup \cdots \cup V_{k} \cup \cdots \cup V_{n-1}$, where $V_{k}$ denotes the interior of the $\eta$-reduced boxes associated with each $k$-simplex; the section $s$ is any smooth approximation of $j^{r}$ valued in $W$. We are ready to perform the isotopy. It is done step by step, in the boxes associated with the vertices of $T^{r}$ first, then with the edges etc. For $x \in \operatorname{star}(\tau)$, lifting the segment $[x, b(\tau)]$ to $\mathcal{F}$ yields a holonomy diffeomorphism between fibres of box

$$
\begin{equation*}
(\text { hol } \mathcal{F})_{x}^{b(\tau)}: B(\tau)_{x} \rightarrow B(\tau)_{b(\tau)} \tag{3.1}
\end{equation*}
$$

which is an $\omega_{0}$-symplectomorphism since $\Omega$ is closed. Similarly, we have the holonomy of $\mathcal{F}_{0}$ which also give an $\omega_{0}$-symplectomorphism. The steps are numbered from 0 to $n$.

If $v$ is a vertex in $T^{r}$, we define $\psi^{0}$ in $B_{\eta}(v)$ by the next formula. For $z \in B_{\eta}(v)$ and $x=p_{1}(z)$,

$$
\begin{equation*}
\psi^{0}(z)=\left(\text { hol } \mathcal{F}_{0}\right)_{v}^{x} \circ(\operatorname{hol} \mathcal{F})_{x}^{v}(z) . \tag{3.2}
\end{equation*}
$$

Since the reduced boxes are disjoint, this formula simultaneously applies to the reduced boxes associated with all vertices. By shrinking the segment $[x, v]$ to $[x, x+t(v-x)]$ and by replacing $v$ with $x+t(v-x)$ in formula (3.2), we define an interpolation between $\psi^{0}(z)$ and $z$. As a consequence $\psi^{0}$ is the time- 1 map of a vertical isotopy of embeddings $\left(\psi_{t}^{0}\right)$ which is easily checked to be symplectic. Since the components of the domain of $\left(\psi_{t}^{0}\right)$ are contractible, this is actually a Hamiltonian isotopy ${ }^{8}$ which therefore extends to a global Hamiltonian isotopy supported in $U$, still denoted by $\left(\psi_{t}^{0}\right)$. Let $\mathcal{F}_{1}$ (resp. $\Omega_{1}$ ) be the direct image of $\mathcal{F}$ (resp. $\Omega$ ) by $\psi_{1}^{0}$; all reduced boxes are transported in this way, becoming $B_{\eta}^{1}(\tau)$ for each $\tau \in T^{r}$. Observe that $\mathcal{F}_{1}$ is horizontal in the reduced new boxes associated with vertices.

The next step (numbered 1) deals with the edges. Let $e$ be an edge in $T^{r}$ with end points $v_{0}, v_{1}$. For $z \in B_{\eta}^{1}(e)$ and $x=p_{1}(z)$, define $\psi^{1}(z)$ by:

$$
\begin{equation*}
\psi^{1}(z)=\left(\text { hol } \mathcal{F}_{0}\right)_{b(e)}^{x} \circ\left(\operatorname{hol} \mathcal{F}_{1}\right)_{x}^{b(e)}(z) . \tag{3.3}
\end{equation*}
$$

Observe that $\psi^{1}(z)=z$ when $z \in B_{\eta}^{1}\left(v_{i}\right), i=0,1$; indeed, this box covers the barycenter $b(e)$ and $\mathcal{F}_{1}$ is horizontal there. Moreover, $\psi^{1}$ is the time- 1 map of a symplectic isotopy $\left(\psi_{t}^{1}\right)$ relative to the reduced boxes of the vertices; this isotopy, called the step-1 isotopy, follows from an interpolation formula analogous to the one defining $\left(\psi_{t}^{0}\right)$.

If $e$ and $e^{\prime}$ are two edges, after condition (2), the domain where their $\eta$-reduced boxes could intersect is contained in a domain where $\mathcal{F}_{1}$ is horizontal and, hence, $\psi_{t}^{1}=I d$ on this domain. Therefore, $\psi_{t}^{1}$ is well defined on the union $V_{1}$ of closed $\eta$-reduced boxes associated with the vertices and edges. Unfortunately, it is not a Hamiltonian isotopy of embeddings; some vertical loops in $V_{1}$ may sweep out some non-zero $\omega_{0}$-area. Thus, it could not extend to an ambient vertical symplectic isotopy. The needed correction is offered by the next claim, following

[^7]well-known ideas (compare V. Colin [3], Lemme 4.4).
CLaim. 1) There is a real combinatorial cocycle $\mu=\mu_{\Omega_{1}}$ of the triangulation $T^{r}$ such that, for each triangle $\tau$, the real number $<\mu, \tau>$ measures the $\omega_{0}$-area swept out by the loop $\{x\} \times\left(\partial \tau^{\perp}\right)$ through the isotopy $\left(\psi_{t}^{1}\right)$ for every $x \in(1-\eta) \operatorname{star}(\tau)$; in particular, this area does not depend on $x$.
2) When $\Omega_{1}$ is exact, $\mu$ is a coboundary.
3) There is an ambient vertical $\omega_{0}$-symplectic isotopy $\left(g_{t}\right)_{t \in[0,1]}$, supported in $U$, which is stationary on $V_{0}$ and such that $\mu_{g_{1}^{*} \Omega_{1}}=0$.

The third item, together with the first item, means that the step- 1 isotopy $\left(\psi_{t}^{1}\right)$ becomes Hamiltonian when $\mathcal{F}_{1}$ stands for the foliation tangent to ker $g_{1}^{*} \Omega_{1}$ instead of ker $\Omega_{1}$.

The proof of the claim is postponed to the end of the section. We first finish the proof of Lemma 3.4 by applying the claim in the next way.

After the step-0 isotopy, the cocycle $\mu_{\Omega_{1}}$ is calculated and the Hamiltonian isotopy $\left(g_{t}\right)$ is derived. Let $\tilde{\mathcal{F}}_{1}$ denote the foliation tangent to ker $g_{1}^{*} \Omega_{1}$; let $\tilde{B}_{\eta}^{1}(\tau):=\left(g_{t}\right)^{-1}\left(B_{\eta}^{1}(\tau)\right)$. Now, the straightening formula 3.3 of the box $\tilde{B}_{\eta}^{1}(e)$ is applied $\tilde{\mathcal{F}}_{1}$ instead of $\mathcal{F}_{1}$. The associated isotopy $\left(\psi_{t}^{1}\right)$ becomes $\omega_{0}$-Hamiltonian. Hence, it extends to a vertical isotopy supported in $U$, denoted likewise, which is $\omega_{0}$-Hamiltonian on each fibre $U_{x}$. This finishes step 1 of the isotopy.

The next steps of the induction are similar, except that the question of being a Hamiltonian isotopy is not raised again since, up to homotopy, every loop in $W$ is already contained in $V_{0} \cup V_{1}$. In the end of this induction, we have a proof of Lemma 3.4 by taking $\psi=\psi_{1}^{n}$.

## Proof of the claim.

1) Let $e$ be an edge of $T^{r}$; its end points are denoted $v_{0}$ and $v_{1}$. Let $x$ be a point in the base of $B_{\eta}(e)$. Set $\gamma:=\{x\} \times e^{\perp}$. We first compute the $\omega_{0}$-area swept out by the vertical arc $\left(\psi_{1}^{1}\right)^{-1}(\gamma)$ through the step-1 isotopy. Denote this area by $\mathcal{A}(x, e)$; any other arc with the same end points would give the same area.

There are two natural "squares", $C$ and $C_{0}$, appearing for this computation. The square $C$ (resp. $C_{0}$ ) is generated by the holonomy of $\mathcal{F}_{1}\left(\right.$ resp. $\mathcal{F}_{0}$ ) over $[b(e), x]$ with initial vertical arc $e^{\perp}$ in the fibre $U_{b(e)}$. They have common horizontal edges: $\beta_{i}:=e \times v_{i}^{\perp}$ for $i=0,1$. Orient $e^{\perp}$ from $v_{0}^{\perp}$ to $v_{1}^{\perp}$; thus, $\gamma$ and $\left(\psi_{1}^{1}\right)^{-1}(\gamma)$ are oriented by carrying the orientation of $e^{\perp}$ by the respective holonomies; and also $C_{0}$ and $C$ are oriented by requiring $\{b(e)\} \times e^{\perp}$ to define the boundary orientation. Then, we have

$$
\begin{equation*}
\mathcal{A}(x, e)=\int_{C} \Omega_{0}-\int_{C_{0}} \Omega_{0} . \tag{3.4}
\end{equation*}
$$

The second summand is 0 by construction. Similarly, we have $\int_{C} \Omega_{1}=0$. Then, if $\Lambda$ is any primitive of $\Omega_{1}-\Omega_{0}$, we derive

$$
\begin{equation*}
\mathcal{A}(x, e)=-\int_{C} d \Lambda \tag{3.5}
\end{equation*}
$$

We now use a specific choice of primitive. Recall the zero-section $Z: \mathbb{S}^{n} \rightarrow U$. For $t \in[0,1]$, let $c_{t}$ denote the contraction $(x, v) \mapsto(x, t v)$ and let $c: U \times[0,1] \rightarrow U$ be the corresponding
homotopy from $Z \circ p_{1}$ to $I d_{U}$. This yields the next formula:

$$
\begin{equation*}
\Omega_{1}-\Omega_{0}=d\left[p_{1}^{*} \theta+\int_{0}^{1} \iota\left(\partial_{t}\right) c^{*}\left(\Omega_{1}-\Omega_{0}\right)\right] \tag{3.6}
\end{equation*}
$$

where $\theta$ is a primitive of the exact form $Z^{*} \Omega_{1}$ (observe that $Z^{*} \Omega_{0}=0$ ); the integral is just the mean value of a one-parameter family of 1 -forms. This primitive of $\Omega_{1}-\Omega_{0}$ also reads

$$
\begin{equation*}
\Lambda_{0}:=p_{1}^{*} \theta+\int_{0}^{1} c_{t}^{*} \iota\left(v \partial_{v}\right)\left(\Omega_{1}-\Omega_{0}\right) \tag{3.7}
\end{equation*}
$$

which vanishes on every vertical vector since $\Omega_{1}$ and $\Omega_{0}$ coincide on the fibres. Orient $\beta_{0}$ as the horizontal lift of $[b(e), x]$ and $\beta_{1}$ as the opposite of the oriented horizontal lift. We have

$$
\begin{equation*}
\int_{C} d \Lambda_{0}=\int_{\beta_{1}} \Lambda_{0}+\int_{\beta_{0}} \Lambda_{0} \tag{3.8}
\end{equation*}
$$

Now, we consider a triangle $\tau$ in $T^{r}$ and we look at the $\omega_{0}$-area $\mathcal{A}(x, \partial \tau)$ swept out by $\{x\} \times(\partial \tau)^{\perp}$ when $x$ belongs to $(1-\delta) \operatorname{star}(\tau)$. The vertices of $\tau$ are denoted by $v_{i}, i=0,1,2$, cyclically ordered; the oriented edges are $e_{j}:=\left[v_{j-1}, v_{j}\right]$ where $j-1$ is taken modulo 3 . There are two particular horizontal lifts of $\left[b\left(e_{j}\right), x\right]$, denoted by $\beta_{j, k}$ with $k=j$ or $j-1$ depending on whether its origin is $\left(b\left(e_{j}\right), v_{j}^{\perp}\right)$ or $\left(b\left(e_{j}\right), v_{j-1}^{\perp}\right)$. If $k=j-1$, it is oriented as $\left[b\left(e_{j}\right), x\right]$; if $k=j$, it has the opposite orientation. By summing up the area swept out by each edge of $\{x\} \times(\partial \tau)^{\perp}$, we have

$$
\begin{equation*}
\mathcal{A}(x, \partial \tau)=<\Lambda_{0}, \beta_{1,1}+\beta_{2,1}+\beta_{2,2}+\beta_{0,2}+\beta_{0,0}+\beta_{1,0}> \tag{3.9}
\end{equation*}
$$

where the bracketing stands for the integration over chain.
Since $\Omega_{1}-\Omega_{0}$ vanishes on $(1-\eta) \operatorname{star}(\tau) \times\left\{v_{i}^{\perp}\right\}$, we have

$$
<\Lambda_{0}, \beta_{i, i}+\beta_{i+1, i}>=<\Lambda_{0},\left[b\left(e_{i}\right), b\left(e_{i+1}\right)\right] \times v_{i}^{\perp}>.
$$

By summation, we have

$$
\begin{equation*}
\mathcal{A}(x, \partial \tau)=\sum_{i}<\Lambda_{0},\left[b\left(e_{i}\right), b\left(e_{i+1}\right)\right] \times v_{i}^{\perp}> \tag{3.10}
\end{equation*}
$$

which implies that $\mathcal{A}(x, \partial \tau)$ does not depend on $x$. The combinatorial cochain $\mu$ is now defined by the next formula:

$$
\begin{equation*}
<\mu, \tau>=\sum_{i}<\Lambda_{0},\left[b\left(e_{i}\right), b\left(e_{i+1}\right)\right] \times v_{i}^{\perp}>. \tag{3.11}
\end{equation*}
$$

If an arbitrary primitive $\Lambda$ of $\Omega-\Omega_{0}$ is used, the above formula becomes

$$
\begin{equation*}
<\mu, \tau>=\sum_{i}<\Lambda,\left\{b\left(e_{i}\right)\right\} \times\left[v_{i-1}^{\perp}, v_{i}^{\perp}\right]>+<\Lambda,\left[b\left(e_{i}\right), b\left(e_{i+1}\right)\right] \times v_{i}^{\perp}>. \tag{3.12}
\end{equation*}
$$

Indeed, a change of primitive consists of adding a closed 1-form; and the integral of this on the polygon $P$ considered in formula (3.12) is zero since $P$ bounds a 2 -cell. ${ }^{9}$

[^8]2) Since $T^{r}$ is a finite simplicial set, we only have to prove that $\left.<\mu, \Sigma\right\rangle=0$ for every 2 -cycle $\Sigma$ of $T^{r}$. Here, the exactness of $\Omega_{1}$ is used. Summing formula (3.12) over all triangles of $\Sigma$ yields a sum of integrals of $\Lambda$ over horizontal polygons in regions where $d \Lambda=0$ (one polygon for each vertex of $\Sigma$ ). Then, these integrals are null. Therefore, there exists a combinatorial 1-cochain $\alpha$ of $T^{r}$ such that $\mu=\partial^{*} \alpha$ where $\partial^{*}$ stands for the combinatorial co-differential.
3) We are going to use this 1 -cochain $\alpha$ in order to correct $\Omega_{1}$ by a certain vertical isotopy. Let $e$ be an oriented edge in $T^{r}$ with origin $v_{-}$and extremity $v_{+}$. The value $\alpha(e)$ is used in the following way. In the fibre over $b(e)$, we find an $\omega_{0}$-Hamiltonian isotopy $\left(g_{t}^{e}\right)_{t \in[0,1]}$, compactly supported in $U_{b(e)}$ and fixing $\left(V_{0}\right)_{b(e)}$, such that the area swept out by the arc $\gamma_{e}:=b(e) \times\left[v_{-}^{\perp}, v_{+}^{\perp}\right]$ is $-\alpha(e) .{ }^{10}$ Observe that the Hamiltonian function is not required to vanish in the fixed domain, but only to be constant on each connected component of the fiber $\left(V_{0}\right)_{b(e)}$ over $b(e)$.

Then, the infinitesimal generator $X_{t}$ of the desired isotopy $\left(g_{t}\right)$ is chosen in finitely many fibres. By a suitable partition of unity there is an extention which is Hamiltonian in each fibre, compactly supported and vanishing in $V_{0}$. Note that the Hamiltonian has to be constant in each connected component of the fibre $\left(V_{0}\right)_{x}$, but these constants may vary with $x$.

The 2-form $g_{1}^{*} \Omega_{1}-\Omega_{1}$ has a primitive associated with the isotopy, named the Poincaré primitive,

$$
\begin{equation*}
A=\int_{0}^{1} g_{t}^{*}\left(\iota\left(X_{t}\right) \Omega_{1}\right) d t \tag{3.13}
\end{equation*}
$$

Since $X_{t}$ vanishes on $V_{0}$, the 1-form $A$ vanishes over here and we have:

$$
\begin{equation*}
<A, \gamma_{e}>=-\alpha(e) \tag{3.14}
\end{equation*}
$$

Now, $\Lambda+A$ is a primitive of $g_{1}^{*} \Omega_{1}-\Omega_{0}$. According to formula (3.12), the combinatorial cochain $\mu_{g_{1}^{*} \Omega_{1}}$ associated with the 2 -form $g_{1}^{*} \Omega_{1}$ vanishes and the claim is proved.

## 4. Parametric family of transversely symplectic $\Gamma_{n}$-Structures

In this section, we prove the parametric version of Theorem 1.5 for the groupoid $\Gamma=\Gamma_{n}^{\text {symp }}$. We emphasize that the required $k$-connectedness of the homotopy fibre $F \pi^{\text {symp }}$ depends only on the dimension of $M$ and not on the number of parameters in the family. Indeed, there is no integrability condition with respect to the parameter. Moreover, we insist that a common jiggling will be used in the proof; its order is bounded by compactness of the parameter space.

We consider the same setting as in Theorem 3.1: $\nu=(E \rightarrow M)$ is a bundle of even rank $n$ over a manifold $M$ of dimension $\leq n+1$ equipped with a $k$-parameter family $\left(\omega_{u}\right)_{u \in \mathbb{D}^{k}}$ of symplectic bilinear forms $\omega_{u}$ on $E$. It is understood that $k$ is positive.

Theorem 4.1. Assume there is a family $\left(\xi_{u}\right)_{u \in \partial \mathbb{D}^{k}}$ of $\Gamma^{\text {symp }}$-structures, namely a family $\left(\Omega_{u}\right)_{u \in \partial \mathbb{D}^{k}}$ of closed 2-forms defined near the zero section $Z$ of $E$, such that $\Omega_{u}$ induces $\omega_{u}$ on the fibres of $\nu$ for every $u \in \partial \mathbb{D}^{k 11}$.

[^9]Then, this family extends over the whole $\mathbb{D}^{k}$ such that $\Omega_{u}$ induces $\omega_{u}$ on the fibres of $\nu$ for every $u \in \mathbb{D}^{k}$. Moreover, the family of cohomology classes $\left[Z^{*} \Omega_{u}\right]_{u \in \mathbb{D}^{k}}$ may be arbitrarily chosen among those which extend the boundary data.

Proof. We start with a cell decomposition $\mathcal{C}$ of $M$ fine enough so that, for every $u \in \partial \mathbb{D}^{k}$ and every cell $C \in \mathcal{C}$, there is a fibered isotopy of $E_{\mid C}$ (depending smoothly on $u$ ) whose time-1 map $\psi_{u}$ satisfies: $\left(\psi_{u}\right)_{*} \Omega_{u}=\theta_{u}^{*} \Omega_{0}$, where $\theta_{u}$ is a linear symplectic trivialization of ( $\nu_{\mid C}, \omega_{u}$ ), depending smoothly on $u \in \mathbb{D}^{k}$, and where $\Omega_{0}$ stands for the pull-back of $\omega_{0}$ by the projection $C \times \mathbb{R}^{n} \rightarrow \mathbb{R}^{n}$.

The theorem will be proved by induction on an order of the simplices of $\mathcal{C}$ for which their dimension is a non-decreasing function. Skipping the intermediate dimensions we jump to the $(n+1)$-cells. Thus, we are reduced to consider the $n$-trivial bundle over $\mathbb{S}^{n}$ and a family $\left(\Omega_{u}\right)$ of exact 2 -forms on a small disK bundle $U$ about the zero section $Z$, which induce the standard form $\omega_{0}$ on each fibre $U_{x}, x \in \mathbb{S}^{n}$, (here a parametric version of Moser's lemma is applied again). This family fulfills the condition that $\Omega_{u}=\Omega_{0}$ for every $u \in \partial \mathbb{D}^{k}$. Let $T$ be a triangulation of $\mathbb{S}^{n}$ and let $T^{r}$ be a Thom subdivision whose order $r$ is large enough so that the same jiggling $j^{r}\left(T^{r}\right)$ fits the proof of Lemma 3.4 for every $u \in \mathbb{D}^{k}$; since the considered family is compact, such an $r$ certainly exists.

Each step of that proof may be performed with parameters using this fixed jiggling. Here it is worth noticing that the vertical isotopy given by Lemma 3.4 is stationary when $\Omega_{u}=\Omega_{0}$, in particular when $u \in \partial \mathbb{D}^{k}$.

The proof of Theorem 1.5 is now completed for the groupoid $\Gamma_{n}^{\text {symp }}$.

## 5. Transversely contact $\Gamma_{n}$-Structures

Here, we prove a theorem which implies Theorem 1.5 for $\Gamma_{n}^{\text {cont }}$-structures. Our setting is not the one of tangential $\Gamma$-structures. It is the following. Given an odd natural integer $n$, a manifold $M$ and a vector bundle $\nu=(E \rightarrow M)$ of rank $n$, we recall that a $\Gamma_{n}^{\text {cont }}$-structure on $M$ with normal bundle $\nu=(E \rightarrow M)$ is given by $\xi=(A, \mathcal{K})$, where $A$ is a 1 -form and $\mathcal{K}$ is a codimension- $n$ foliation, both defined near the 0 -section $Z$ in $E$, such that:

- $A \wedge d A^{\frac{n-1}{2}}$ induces a germ of volume form on $E_{x}$ for every $x \in M$;
$-\operatorname{ker}\left(A \wedge d A^{\frac{n-1}{2}}\right)=T \mathcal{K}$;
$-\operatorname{ker} A$ contains $T \mathcal{K}$ and is invariant by the holonomy of $\mathcal{K}$.
As in the symplectic case, the next Theorem was known to A. Haefliger [8] when $\operatorname{dim} M<$ $n+1$ and to D. McDuff [13] when $\operatorname{dim} M=n+1$.

Theorem 5.1. Assume $M$ is a manifold of dimension not greater than the rank of the vector bundle $\nu$. Let $(\alpha, \beta)$ be formal contact data, that is, a section $\alpha$ of $\nu^{*}$ and a section $\beta$ of $\wedge^{2} \nu^{*}$ such that $\alpha \wedge \beta^{\frac{n-1}{2}}$ is a non-vanishing section of $\wedge^{n} \nu^{*}$. Then, there exists a $\Gamma_{n}^{\text {cont }}$-structure $\xi=(A, \mathcal{K})$ on $M$ with normal bundle $\nu$ such that, for all $x \in M$, the next two conditions are fulfilled:

$$
\left\{\begin{array}{l}
\operatorname{ker} A_{Z(x)} \cap \nu_{x}=\operatorname{ker} \alpha(x)  \tag{5.1}\\
(d A)_{Z(x)}=\beta(x) .
\end{array}\right.
$$

Moreover, this statement holds true in a relative parametric version.
Proof. For simplicity, we do not formulate any homotopy statement at the level of classifying spaces. Nevertheless, the strategy of proof is similar to the one we used for $\Gamma_{n}^{\text {symp }}$-structures. It is even simpler since every contact isotopy is Hamiltonian.

Let us first consider the non-parametric version. The construction of $\xi$ is performed step by step over each cell of a cell decomposition of $M$. We are looking on the last $n$-cell $e^{n}$ only. Let $C:=\partial e^{n} \times[0,1] \cong \mathbb{S}^{n-1} \times[0,1]$ be a collar neighborhood of the boundary, on which we are given a $\Gamma_{n}^{\text {cont }}$-structure $\xi=(A, \mathcal{K})$ which fufills (5.1).

Since the formal data $(\alpha, \beta)$ extends over $e^{n}$, there is a trivialization of $\nu$ over $e^{n},\left(p_{1}, p_{2}\right)$ : $E \mid e^{n} \rightarrow e^{n} \times \mathbb{R}^{n}$, in which $(\alpha(x), \beta(x))$ is independent of $x \in e^{n}$. On $\mathbb{R}^{n}$ equipped with $(\alpha, \beta)$, we may think of $\beta$ as a closed differential form with constant coefficients; by taking a primitive, we have a unique contact form $\alpha_{0}$ such that :

$$
\left\{\begin{array}{l}
\alpha_{0}(0)=\alpha  \tag{5.2}\\
d \alpha_{0}=\beta
\end{array}\right.
$$

We derive a trivial $\Gamma_{n}^{\text {cont }}$-structure $\xi_{0}=\left(A_{0}, \mathcal{K}_{0}\right)$ on $e_{n}$ such that

$$
\left\{\begin{array}{l}
A_{0}=p_{2}^{*}\left(\alpha_{0}\right)  \tag{5.3}\\
d A_{0}=p_{2}^{*}\left(d \alpha_{0}\right)
\end{array}\right.
$$

Hence, $\mathcal{K}_{0}$ is the horizontal foliation. Now, there is a Moser type lemma ${ }^{12}$ which we are going to present below. This allows us to perform some vertical isotopy which reduces to the case where, in a small tube $U$ about the zero section and for every point $x \in C$, we have

$$
\begin{equation*}
A_{\mid U_{x}}=A_{0 \mid U_{x}} \tag{5.4}
\end{equation*}
$$

Lemma 5.2. Let $\left(\alpha_{t}\right)_{t \in[0,1]}$ be a path of contact forms in a manifold $V^{n}$. Let $L$ be a hypersurface in $V$. It is assumed that the Reeb vector field $R_{t}$ of $\alpha_{t}$ is never tangent to $L$. Then, we have the following:

1) The next equation whose unknown is $X_{t}$ can be solved near $L$ :

$$
\begin{equation*}
L_{X_{t}} \alpha_{t}+\dot{\alpha}_{t}=0 \tag{5.5}
\end{equation*}
$$

2) Let $\left(\alpha_{t}\right)_{t \in[0,1]}$ be a path of germs in $\left(\mathbb{R}^{2 p+1}, 0\right)$ of contact forms. If $\operatorname{ker} \alpha_{t}(0)$ is independent of $t$, then these germs are isotopic.
3) The previous statements hold true with parameters and in a relative version.

Proof. 1) The vector $X_{t}$ decomposes as $X_{t}=Y_{t}+Z_{t}$ with $Y_{t} \in \operatorname{ker} \alpha_{t}$ and $Z_{t}=\alpha_{t}\left(X_{t}\right) R_{t}$. Let us recall that $R_{t}$ generates in each point the kernel of $d \alpha_{t}$. Then, Equation (5.5) becomes the following system:

$$
\left\{\begin{array}{c}
R_{t} \cdot\left(\alpha_{t}\left(X_{t}\right)\right)+\dot{\alpha}_{t}\left(R_{t}\right)=0  \tag{5.6}\\
\iota\left(Y_{t}\right)\left(d \alpha_{t \mid \operatorname{ker} \alpha_{t}}\right)+d\left(\alpha_{t}\left(X_{t}\right)\right)_{\mid \operatorname{ker} \alpha_{t}}+\dot{\alpha}_{t \mid \operatorname{ker} \alpha_{t}}=0
\end{array}\right.
$$

Fix $t \in[0,1]$. The first equation of this system is a differential equation along the orbits of $R_{t}$ whose unknown function is $\alpha_{t}\left(X_{t}\right)$. It has a unique solution if $\alpha_{t}\left(X_{t}\right)$ is required to equal

[^10]0 along $L$ (here the transversality assumption is used). Then, the component $Z_{t}$ of $X_{t}$ is determined. Once $\alpha_{t}\left(X_{t}\right)$ is known, the second equation of (5.6) has a unique solution since the form induced by $d \alpha_{t}$ on ker $\alpha_{t}$ is symplectic.
2) Here $L$ is the hyperplane which is the common kernel of the contact forms in the considered path. Replace the germs with genuine representatives. Following the solution of 1), we have $X_{t}(0)=0$ for every $t \in[0,1]$. Therefore, the flow $\varphi_{t}$ of $X_{t}$ keeps the origin fixed. It is well defined on some neighborhood of the origin up to $t=1$ and it is the identity on $L$. We deduce from Equation (5.5) that the following is satisfied near the origin for every $t \in[0,1]$ :

$$
\begin{equation*}
\varphi_{t}^{*}\left(L_{X_{t}} \alpha_{t}+\dot{\alpha}_{t}\right)=0 \tag{5.7}
\end{equation*}
$$

and the latter is obtained by taking the time derivative of the next equation

$$
\begin{equation*}
\varphi_{t}^{*} \alpha_{t}=\alpha_{0} . \tag{5.8}
\end{equation*}
$$

So, the desired isotopy is obtained by integrating $X_{t}$.
3) Considering the equations which are solved, this claim is clear.

We continue the proof of Theorem 5.1. In order to derive (5.4) from Lemma 5.2, we use $x \in C$ as a parameter and, in each fibre $E_{x}$, we consider $\alpha_{t}=t A_{\mid E_{x}}+(1-t) A_{0 \mid E_{x}}$. Due to the formal data, $\alpha_{t}$ is a contact form near the origin of $E_{x}$ for every $t \in[0,1]$.

After this Moser type reduction, we have to state and prove a lemma similar to Lemma 3.4. Actually, it is not useful to write it down explicitly since it is the same: the holonomy maps are contactomorphisms; thus, in each fibre of a box the vertical isotopy preseves the contact distribution ker $A_{0} \cap E_{x}$. Then, it is Hamiltonian with respect to $A_{0} \mid E_{x}{ }^{13}$. Therefore, it extends globally since extending such an isotopy amounts to extend its Hamiltonian function; thus, no obstruction is encountered. This finishes the proof of the non-parametric version.

For the relative parametric version of Theorem 5.1, we have to consider a family $\left(\alpha_{u}, \beta_{u}\right)_{u \in \mathbb{D}^{k}}$ which underlies a family of $\Gamma_{n}^{\text {cont }}$-structures when $u \in \partial \mathbb{D}^{k}$. Thanks to the relative parametric version of Lemma 5.2, we may follow word for word the proof we gave for $\Gamma_{n}^{\text {symp }}$.

## 6. Open manifolds

This section is devoted to the proof of Theorem 1.9. Let us recall the setting: $\Gamma$ is an open subgroupoid of the structural groupoid $\Gamma(X)$ of a model $n$-manifold $X$ (see Section 1 ); $M$ is an open manifold of dimension $n$ and $\xi \in H_{\tau M}^{1}(M ; \Gamma)$ is a $\Gamma$-structure on $M$ whose normal bundle is $\tau M$, the tangent space to $M$. Let $T M$ denote its total space and $Z: M \rightarrow T M$ denote the 0 -section. The associated $\Gamma$-foliation defined near $Z(M)$ in $T M$ is denoted by $\mathcal{F}=\mathcal{F}_{\xi}$. We recall a topological fact about open manifolds whose proof is available in [5] Section 4.3.
Proposition 6.1. Given an open $n$-manifold $M$, there exists an $(n-1)$-polyhedron $K \subset M$, called $a$ spine of $M$, so that the inclusion is a homotopy equivalence. More precisely, for any

[^11]regular neighborhood $V$ of $K$, there exists a compressing isotopy of embeddings $f_{t}: M \rightarrow M, t \in$ $[0,1]$, from $I d_{M}$ to an embedding $f_{1}: M \rightarrow V$, which is stationary on a neighborhood of $K$ and such that $t^{\prime}>t$ implies $f_{t^{\prime}}(M) \subset f_{t}(M)$.

We are going to prove the next statement from which Theorem 1.9 will be easily derived.
Theorem 6.2. Let $K \subset M$ be an $(n-1)$-dimensional polyhedron in an n-manifold $M$ (open or closed). Let $\xi_{s}, s \in \mathbb{D}^{k}$, be a $k$-parameter family of $\Gamma$-structures on $M$ with normal bundle $\tau M$. When $s \in \partial \mathbb{D}^{k}$, it is assumed that the associated foliation $\mathcal{F}_{s}$ is tangent to $\mathcal{F}_{\text {exp }}$ along $Z(M)$. Then, there exist an open neighborhood $V$ of $K$ in $M$ and a $k$-parameter family $\bar{\xi}_{s}$ of $\Gamma$-structures on $M \times[0,1]$ - that is, concordances of $\xi_{s}$ - such that:
$-\bar{\xi}_{s}\left|V \times\{0\}=\xi_{s}\right| V$;

- $\bar{\xi}_{s} \mid V \times\{1\}$ is regular and its associated foliation is tangent to $\mathcal{F}_{\text {exp }}$;
- $\bar{\xi}_{s}=p_{1}^{*}\left(\xi_{s} \mid V\right)$ for every $s \in \partial \mathbb{D}^{k}$, where $p_{1}$ denotes the projection $M \times[0,1] \rightarrow M$.

In other words, $\left(\bar{\xi}_{s}\right)_{s \in \mathbb{D}^{k}}$ is a family of regularization concordances on a neighborhood of a $K$, relative to the boundary of the parameter space.
6.3. Proof of Theorem 1.9 from Theorem 6.2. Here, $M$ is an open manifold. A spine $K$ of $M$ may be chosen (Proposition 6.1) and Theorem 6.2 applies to these data: $K \subset M,\left(\xi_{s}\right)_{s \in \mathbb{D}^{k}}$. So, we have a family $\bar{\xi}_{s}$ of regularization concordances on some neighborhood $V$ of $K$ in $M$, relative to $\partial \mathbb{D}^{k}$. We have to extend this family to a family of regularization concordances over the whole of $M$, still relative to $\partial \mathbb{D}^{k}$. We may assume there exists $\rho$ close to 1 so that $\xi_{s}$ is regular on $M$ when $\|s\| \in[\rho, 1]$.

We first insert the family of concordances described as follows, where $t \in[0,1]$ is the parameter of the concordance:

- for $\|s\| \leq \rho$, we put the concordance $t \mapsto f_{t}^{*} \xi_{s}$, where $\left(f_{t}\right)_{t \in[0,1]}$ is the isotopy of embeddings given by Proposition 6.1;
- for $\rho \leq\|s\| \leq 1$, we put the concordance $t \mapsto f_{\left(\frac{1-\|s\|}{1-\rho} t\right)}^{*} \xi_{s}$.

When $t=1$ (that is the end of these concordances depending on $s \in \mathbb{D}^{k}$ ) and when $\|s\| \geq \rho$, the structures are regular on $M$. Then, denoting by $S:[1,2] \rightarrow[0,1]$ the shift $t \mapsto t-1$, we continue, for $t \in[1,2]$ with the concordances $\left(f_{1} \times S\right)^{*} \bar{\xi}_{s}$ when $\|s\| \leq \rho$; these ones are stationary when $\|s\|=\rho$. Thus, we are allowed to extend them by the stationary concordances when $\rho \leq\|s\| \leq 1$. Of course, the previous piecewise description can be made smooth if desired.

### 6.4. Proof of Theorem 6.2 without parameters $(k=0)$.

We start with a $\Gamma$-structure $\xi$ on $M$. Let $\mathcal{F}$ be its associated $\Gamma$-foliation defined in some small neighbohood $U$ of $Z(M)$. Let $\xi^{u}$ (resp. $\mathcal{F}^{u}$ ) be the underlying $\Gamma_{n}$-structure (resp. $\Gamma_{n}$-foliation) of $\xi$ (resp. $\mathcal{F}$ ) where the transverse geometry is forgotten.

The proof will consist of two steps: in the first step, we will make a specific regularization of $\xi^{u}$ by some $\Gamma_{n}$-concordance over $M \times[0,3]$; in the second step, the geometric $\Gamma$-structure of the concordance will be defined only over a small neighborhood of $K \times[0,3]$. Finally, we get the $\Gamma$-regularization of $\xi$ near $K$.

1st step. Fix a small $\varepsilon>0$. As in Thurston [19], we consider a one-parameter family $P_{t}$, $t \in[0,3]$, of $n$-plane fields on $U$ with the following properties:

- $P_{t}$ is transverse to the fibres for every $t$.
- $P_{t}$ is tangent to $\mathcal{F}$ when $t \in[0,1+\varepsilon]$.
- $P_{t}$ is tangent to $\mathcal{F}_{\text {exp }}$ when $t \in[2,3]$.

Such a plane field exists by barycentric combination in the convex set ${ }^{14}$ of the plane fields transverse to the fibres of $\tau M$.

Let $T$ be a triangulation of $M$ containing a subdivision of $K$ (also called $K$ ) as a sub-complex and fine enough with respect to the open covering $\left\{\exp _{x}\left(U_{x}\right) \mid x \in M\right\}$ in order that formula (2.2) makes sense. Here, we recall that formula which holds for $x$ in any simplex of $T$ :

$$
\exp _{x}\left(j^{r}(x)\right)=\sigma^{r}(x)
$$

We now consider the Thom jiggling given by formula (2.2); its order $r$ is chosen large enough so that the $n$-simplices of $j^{r}\left(T^{r}\right)$ are transverse to $P_{t}$ for every $t \in[0,3]$.

The first piece of the concordance, when $t \in[0,1+\varepsilon]$, actually a $\Gamma$-concordance, consists of moving the zero section from $Z$ to $j^{r}$ by traversing any homotopy valued in $U$ and stationary when $t \in[1,1+\varepsilon]$. The concordance of $\Gamma$-structure is given by pulling $\xi$ back by this homotopy of maps $M \rightarrow U$ (look at Remark 2.6 1) about smoothness).

We now describe the second piece of the concordance, when $t \in[1,2]$. We consider the codimension $n$-plane field $\tilde{P}$ in $U \times[0,3]$ defined by

$$
\begin{equation*}
\tilde{P}(x, t):=P_{t}(x) \oplus \mathbb{R} \partial_{t} . \tag{6.1}
\end{equation*}
$$

It is tangent to $\mathcal{F} \times[0,1+\varepsilon]$ and to $\mathcal{F}_{\text {exp }} \times[2,3]$. The trace of $\tilde{P}$ on each $(n+1)$-cell of $j^{r}(M) \times[1,2]$ is one-dimensional. Then, this trace is integrable. Thus, there is a $C^{0}$-small smooth approximation of $\tilde{P}$, relative to $t \in[0,1] \cup[2,3]$ and still denoted by $\tilde{P}$, which is integrable near $j^{r}(M) \times[1,2]$. Now, the pair $\left(j^{r}(M) \times[1,2], \tilde{P}\right)$ defines a concordance of $\Gamma_{n^{-}}$ structure $s$. This finishes the second piece.

The third piece of the concordance when $t \in[2,3]$ consists of keeping the foliation $\mathcal{F}_{\text {exp }}$ and applying the homotopy from $j^{r}$ to the 0 -section $Z$ as provided by Proposition 2.52 ). On the whole, we built a specific regularization concordance of the underlying $\Gamma_{n}$-structure $\xi^{u}$, which is nearly sufficient for our purpose.

We need more of good position. Let $K^{r}$ denote the $(n-1)$-dimensional complex which is the $r$-th Thom subdivision of $K$. Let $\tilde{K}^{r}$ be the image of $Z\left(K^{r}\right) \times[0,3]$ along the concordance built above. This is an $n$-complex whose $n$-cells are not transverse to $\tilde{P}$. When $t \in[1,2]$, the only reason for non-transversality is that $\tilde{K}^{r}$ and $\tilde{P}$ share the $\partial_{t}$-direction. Let $\tilde{K}_{\left[t, t^{\prime}\right]}^{r}\left(\right.$ resp. $\left.\tilde{K}_{t}^{r}\right)$ denote the restriction of $\tilde{K}^{r}$ over $M \times\left[t, t^{\prime}\right]$ (resp. $M \times\{t\}$ ).

When the $n$-cells of $\tilde{K}_{\left[t, t^{\prime}\right]}^{r}$ are prismatic (that is, simplex $\times$ interval) which is always the case when $\left[t, t^{\prime}\right] \subset[1,2]$, they will receive the standard subdivision defined by H. Whitney ([21], Appendix II) ${ }^{15}$; this latter only depends on an order chosen on the set of vertices of $\tilde{K}_{t}^{r}$.

[^12]CLAIM. There exist a subdivision $t_{1}=1, t_{1}^{\prime}, \ldots, t_{i}, t_{i}^{\prime}, \ldots, t_{N}=3$ and a small piecewise smooth vertical isotopy, its time-one map being denoted by $\psi$, such that:
(i) $\psi \mid \tilde{K}_{t_{i}}^{r}=I d$ for every $i=1, \ldots, N$;
(ii) for every n-simplex $\tau$ of the standard subdivision of $\tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}$ (resp. $\tilde{K}_{\left[t_{i}^{\prime}, t_{i+1}\right]}^{r}$ ), the image $\psi(\tau)$ is smoothly embedded in $U \times[0,1]$ and quasi-transverse to $\tilde{P}$. Here, quasitransverse means transverse when $\operatorname{dim} \tau \geq n$ and no tangency when $\operatorname{dim} \tau<n$.
Proof of the claim. We search for a jiggling in time. We are going to do it for $\tilde{K}_{[1,2]}^{r}$; the jiggling in time of $\tilde{K}_{[2,3]}^{r}$ is similar, but a bit more complicated due to the fact that the cell decomposition is not purely prismatic. A numbering of the vertices of $\tilde{K}_{1}^{r}$ is fixed: $v_{1}, v_{2}, \ldots$; this numbering propagates to the corresponding vertices of $\tilde{K}_{t}^{r}$ for every $t \in[1,2]$.

The time subdivision is chosen so that, for every $(n-1)$-simplex $c \subset \tilde{K}_{t}^{r}$ and every $x \in c$, the hyperplane $H_{t}(x, c):=T_{x}(c)+P_{t}(x)$ varies very little in $T U$ when $t$ traverses $\left[t_{i}, t_{i+1}\right]$, uniformly when $x$ runs in any star. Let $t_{i}^{\prime}$ be the middle of this interval. Each $\tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}$ (resp. $\left.\tilde{K}_{\left[t_{i}^{\prime}, t_{i+1}\right]}^{r}\right)$ receives the standard subdivision of the prismatic cells. On $\tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}$, the desired embedding $\psi$ and its isotopy from $I d$ are constructed recursively on the numbered stars of vertices $\operatorname{star}\left(v_{1}\right)$, star $\left(v_{2}\right), \ldots$ Precisely, there is a locally finite family of isotopies $\chi_{1}, \chi_{2}, \ldots$ (that is, only finitely many supports intersect) and $\psi$ will be the composition of their time-one map: $\cdots \circ \chi_{2}^{1} \circ \chi_{1}^{1}$. The reversed isotopies are used over the interval $\left[t_{i}^{\prime}, t_{i+1}\right]$.

Let $v_{1}$ be the first vertex of $\tilde{K}_{t_{i}}^{r}$. Let $X_{1}$ be a small vertical vector in $T_{v_{1}} U$ which is chosen linearly independent form all above-mentioned hyperplanes $H_{t_{i}}(x, c)$ where $c$ is any $n$-simplex of $\tilde{K}_{t_{i}}^{r}$ passing through $v_{1}$. Let $v_{1}^{\prime}$ be the corresponding vertex in $\tilde{K}_{t_{i}^{\prime}}^{r}$. By definition of the standard subdivision of $\tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}$, the vertex $v_{1}^{\prime}$ is joined to $\operatorname{star}\left(v_{1}, \tilde{K}_{t_{i}}^{r}\right)$, the star of $v_{1}$ in $\tilde{K}_{t_{i}}^{r}$. In affine notation $\chi_{1}^{1}$ is obtained by replacing in $\tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}$

$$
\begin{equation*}
\operatorname{star}\left(v_{1}^{\prime}, \tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}\right) \quad \text { with } \quad\left(v_{1}^{\prime}+X_{1}\right) * l k\left(v_{1}^{\prime}, \tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}\right) \tag{6.2}
\end{equation*}
$$

where $l k(a,-)$ stands for the link of $a$, that is, the union of simplices in $\operatorname{star}(a,-)$ which do not contain $a$. After this step, we get the property that every $n$-simplex in $B_{1}:=\chi_{1}^{1}\left(\tilde{K}_{\left[t_{i}, t_{i}^{\prime}\right]}^{r}\right)$ passing through $v_{1}^{\prime}+X_{1}$ is transversal to $\tilde{P}$.

The second step consists of a similar construction related to the star of $v_{2}^{\prime}$ in $B_{1}$ by using a small vertical vector $X_{2}$ which is linearly independent of the hyperplanes made with the $n$-simplices of $B_{1}$ passing through $v_{2}^{\prime}$. This yields $\chi_{2}^{1}$, the time-one map of the second isotopy which allows us to gain the transversality of new $n$-simplices to $\tilde{P}$. When $\operatorname{star}\left(v_{2}^{\prime}, B_{1}\right)$ meets $\operatorname{star}\left(v_{1}^{\prime}+X_{1}, B_{1}\right)$, the vector $X_{2}$ is chosen so small that the property gained in the first step is preserved. And so on.

In what follows, we still denote by $\tilde{K}^{r}$ the outcome of the previous jiggling. As a result, every $n$-cell of $\tilde{K}_{[1,3]}^{r}$ is transverse to $\tilde{P}$. This simplicial complex $\tilde{K}^{r}$ collapses ${ }^{16}$ successively to

[^13]$\tilde{K}_{[0,2]}^{r}$ and then to $\tilde{K}_{[0,1]}^{r}$.

2ND STEP.
We now focus on $\tilde{K}_{[0,1]}^{r}$ on which $\tilde{K}^{r}$ collapses. Since the cells of $\tilde{K}_{[1,3]}^{r}$ of positive dimension are quasi-transverse to the foliation $\tilde{P}$, the collapse $\tilde{K}^{r} \searrow \tilde{K}_{[0,1]}^{r}$ extends to a collapse of pair

$$
\begin{equation*}
\left(\tilde{K}^{r}, \tilde{P}\right) \searrow\left(\tilde{K}_{[0,1]}^{r}, \tilde{P}\right) . \tag{6.3}
\end{equation*}
$$

Let $N\left(\tilde{K}^{r}\right)$ denote a small neighborhood of $\tilde{K}^{r}$ in $U \times[0,3]$. From the sequence of elementary collapses, one derives step by step an embedding of pair

$$
\begin{equation*}
\Phi:\left(N\left(\tilde{K}^{r}\right), \tilde{P}\right) \rightarrow(U \times[0,1+\varepsilon), \mathcal{F} \times[0,1+\varepsilon)) \tag{6.4}
\end{equation*}
$$

which induces the inclusion $N\left(\tilde{K}_{[0,1]}^{r}\right) \hookrightarrow U \times[0,1+\varepsilon)$. Since $\mathcal{F} \times[0,1+\varepsilon]$ is a $\Gamma$-foliation, $\tilde{P}_{\mid N\left(\tilde{K}^{r}\right)}$ is so by pulling back through $\Phi$. Therefore, $\Phi^{*}(\mathcal{F} \times[0,1+\varepsilon))$ is a regularization concordance of the $\Gamma$-structure which is induced near $K$.

This last process associated with collapses is named inflation in W. Thurston's article [19].
6.5. Relative parametric version of Theorem 6.2. Here, the data consist of a family $\left(\xi_{s}\right)_{s \in \mathbb{D}^{k}}$ of $\Gamma$-structures whose normal bundle is the tangent bundle $\tau M$. It is assumed that, for every $s \in \partial \mathbb{D}^{k}$, the associated foliation $\mathcal{F}_{s}$ is tangent to $\mathcal{F}_{\text {exp }}$ along the 0 -section $Z(M)$, hence $\xi_{s}$ is regular. Without loss of generality, we may assume $\xi_{s}$ is regular when $1 \geq\|s\| \geq \rho$ for some $\rho$ close to 1 . The proof just consists of two remarks.

1) The previous proof (see Subsection 6.4) works directly for our $k$-parameter family of data if we do not take care of the boundary condition. Indeed, observe that a common order $r$ of Thom jiggling $j^{r}$ can be chosen for all $s \in \mathbb{D}^{k}$ since the family of $n$-plane fields $P_{s, t}$ we have to look at is compact. Thus, if the jiggling is vertical enough, that is, for $r$ large enough, its $n$-simplices are transverse to $P_{s, t}$ for every $(s, t) \in \mathbb{D}^{k} \times[0,3]$. The 0 -parameter process applies for every $s \in \mathbb{D}^{k}$ and yields a regularization in a fixed neighborhood $V$ of $K$ in $M$. Precisely, we have formulas (6.3) and (6.4) depending on the parameter $s \in \mathbb{D}^{k}$, yielding regularization concordances $\Phi_{s}^{*}\left(\mathcal{F}_{s} \times[0,1+\varepsilon)\right)$.
2) We may assume that $P_{s, t}$ is tangent to $\mathcal{F}_{s}$ for every $s \in\{1 \geq\|s\| \geq \rho\}$ and $t \in[0,3]$. For $\|s\| \in[\rho, 1]$, set $\mu(s):=\frac{1-\|s\|}{1-\rho}$. Recall that $\Phi_{s}$ is the time-one map of an isotopy of embeddings $\Phi_{s}^{w}: N\left(\tilde{K}^{r}\right) \rightarrow U \times[0,3], w \in[0,1]$, relative to $N\left(\tilde{K}_{[0,1]}^{r}\right)$ and such that $\Phi_{s}^{0}=I d$ and $\Phi_{s}^{1}\left(N\left(\tilde{K}^{r}\right)\right) \subset N\left(\tilde{K}_{[0,1+\varepsilon]}^{r}\right)$.

We finish, for $s \in\{1 \geq\|s\| \geq \rho\}$, with the regularization concordance $\left(\Phi_{s}^{\mu(s)}\right)^{*}\left(\mathcal{F}_{s} \times[0,3]\right)$. When $\|s\|=1$, this is the trivial concordance $\mathcal{F}_{s} \times[0,3]$. Then, the relative version is proved.

Acknoledgments. We thank Howard Jacobowitz and Peter Landweber who have expressed their interest towards our article and sent to us some valuable remarks. We are deeply grateful to the anonymous referee for his exceptionally careful reading and for having suggested to us many improvements of writing.
