Electromagnetic modeling of waveguide amplifier based on Nd$^{3+}$ Si-rich SiO$_2$ layers by means of the ADE-FDTD method

Christian Dufour*, Julien Cardin, Olivier Debieu, Alexandre Fafin and Fabrice Gourbilleau

Abstract
By means of ADE-FDTD method, this paper investigates the electromagnetic modelling of a rib-loaded waveguide composed of a Nd$^{3+}$ doped Silicon Rich Silicon Oxide active layer sandwiched between a SiO$_2$ bottom cladding and a SiO$_2$ rib. The Auxiliary Differential Equations are the rate equations which govern the levels populations. The Finite Difference Time Domain (FDTD) scheme is used to solve the space and time dependent Maxwell equations which describe the electromagnetic field in a copropagating scheme of both pumping ($\lambda_{\text{pump}} = 488$ nm) and signal ($\lambda_{\text{signal}} = 1064$ nm) waves. Such systems are characterized by extremely different specific times such as the period of electromagnetic field $\sim 10^{-15}$ s and the lifetimes of the electronic levels between $\sim 10^{-10}$s and $\sim 10^{-4}$ s. The time scaling method is used in addition to specific initial conditions in order to decrease the computational time. We show maps of the Poynting vector along the propagation direction as a function of the silicon nanograin (Si-ng) concentrations. A threshold value of $10^{24}$ Si-ng m$^{-3}$ is extracted below which the pump wave can propagate so that a signal amplification is possible.

Keywords: Silicon nanograin, Silica, Neodymium, ADE-FDTD, Waveguide, amplification

Introduction
The feasibility of optical amplifying waveguide has been for almost two decades the purpose of numerous experimental works [1]. The devices under study were based on an active layer constituted of a silica film co-doped with silicon nanograins (Si-ng) and rare earth ions RE (Er$^{3+}$ in particular) deposited on a substrate and covered by a cladding layer of pure silica. The differences in the optical indices of the three layers ensure the optical guiding. The amplification of a signal is based on an efficient population inversion of the rare earth levels whose energy difference correspond to the signal wavelength. Due to the very low RE signal absorption cross section, a solution has been found using silicon nanoparticles. The physical background lies on two major phenomena: on the one hand, the ability of Si-ng’s to absorb efficiently a pumping light and, on the other hand, the effective energy transfer between Si-ng’s and RE ions. In this way, a RE population inversion could have been achieved in order to fulfill the amplification function of the device. Despite all these promising features, a net gain is hardly achievable with the former Er$^{3+}$ ions due to their great probability of signal reabsorption from the ground state. This drawback is prevented with the use of Nd$^{3+}$ ions described by a five level scheme since the transition does not involve the ground state. The theoretical studies of the waveguide amplifiers have accounted for both rate population equations and Maxwell equations. In this paper we investigate the ADE-FDTD method applied to a rib-loaded waveguide whose active layer is composed of a silica film co doped with Nd$^{3+}$ ions and silicon nanograins. One of the main issues to be addressed in such systems consists in dealing with extremely different time scales: the populations lifetimes (1 ms) and the electromagnetic field period ($10^{-15}$ s). According to [2,3] we use a time scaling that allows to circumvent this issue. All the lifetimes have been shortened by a factor of $10^{6}$, and consequently the transfer coefficient K has also been divided by the same coefficient. In this paper, we investigate the accuracy of this scaling method through longitudinal and trans-verse maps of the Poynting vector for
several Si-ng concentrations. The applicability of this method is linked to the space and time calculation steps since a reasonable computing time must not be exceeded.

**Computational details**

We treat the problem within a calculation box as described in Figure 1. Each axis (x, y and z) is divided into space steps (Δx, Δy and Δz respectively).

Four zones appear and will be described hereafter: i) the rib-loaded waveguide composed of the active layer (optical index n_{act} = 1.52) stacked between the SiO_{2} cladding and rib (optical index n_{SiO_{2}} = 1.45), ii) the plane containing the electromagnetic field source (\varepsilon_{source} = 6 Δz), iii) the diaphragm (between 7Δz and 10Δz) which transforms the source into a realistic electromagnetic Gaussian field impinging on the waveguide and iv) the boundary zone (PML) (4Δz in thickness) characterized by appropriate values of electrical (\rho) and magnetic (\sigma) conductivities in order to absorb the electromagnetic field so that the box borders do not influence the field in the zone of interest [4].

**Lorentz Model for the dielectric susceptibility**

Considering a transition between levels i and j we use the Lorentz following relationship which makes the coupling between the polarization density \mathbf{P}_{ij}, the level populations \mathbf{N}_{i} and \mathbf{N}_{j} in m^{-3} and the total electric field \mathbf{E}:

$$\frac{d^{2}P_{ij}(t)}{dt^{2}} + \Delta \omega_{ij} \frac{dP_{ij}(t)}{dt} + \omega_{ij}^{2}P_{ij}(t) = \kappa \Delta N_{ij}(t)E(t)$$

(1)

\(\Delta \omega_{ij}\) is the FWHM of the \(ij\) transition deduced from photoluminescence measurements according to [5], \(\omega_{ij} = \frac{2\pi c}{\lambda_{ij}}\) is the oscillator pulsation linked to the \(ij\) transition wavelength \(\lambda_{ij}\), \(\kappa = \frac{6\pi \varepsilon_{0}c^{3}Y_{ij}}{\omega_{ij}^{6}}\) and \(Y_{ij}\) is the \(ij\) radiative transition rate in s^{-1} [6,7]. The level populations difference in m^{-3} is given by \(\Delta N_{ij} = N_{ij} - N_{ji}\).

In the same way, we describe the polarisation density \(\mathbf{P}_{si}\) linked to the silicon level populations \(N_{Si}\) (ground level) and \(N_{Si}^{\star}\) (excited level), to the oscillator pulsation \(\omega_{Si}\) and finally to the transition FWHM \(\Delta \omega_{Si}\).

**Maxwell equations: FDTD numerical method**

We start from the Maxwell equation which links the displacement vector \(\mathbf{D}\) to the magnetic excitation \(\mathbf{H}\):

$$\frac{\partial \mathbf{D}}{\partial t} = \nabla \times \mathbf{H} - \mathbf{J}\_c$$

where the current density \(\mathbf{J\_c}\) is related to \(\mathbf{E}\) by \(\mathbf{J\_c} = \sigma \mathbf{E}\)

where \(\sigma\) is the electrical conductivity. Accounting for the relationship between \(\mathbf{D}\) and the total polarisation density, \(\mathbf{D} = \varepsilon_{0} \mathbf{E} + \sum \mathbf{P}_{ij}\) we may write:

$$\frac{\partial \mathbf{E}}{\partial t} = \frac{1}{\varepsilon_{0}\varepsilon_{r}} \nabla \times \mathbf{H} - \frac{\sigma}{\varepsilon_{0}\varepsilon_{r}} \mathbf{E} - \frac{1}{\varepsilon_{0}\varepsilon_{r}} \frac{\partial}{\partial t} \left( \sum \mathbf{P}_{ij} \right)$$

(2)

$$\frac{\partial \mathbf{H}}{\partial t} = \frac{1}{\mu} \nabla \times \mathbf{E} - \frac{\rho}{\mu} \mathbf{H}$$

(3)

All the calculations are performed with real variables. Hence, in order to account for absorption processes other than those due to the level transitions, we characterize (especially for the diaphragm and PML) a specific electric conductivity \(\sigma\) and magnetic conductivity \(\rho\).

Both equations 2 and 3 are solved using the Yee algorithm [8]. The space steps are chosen so that:

\(\Delta x = \Delta y = \Delta z \ll \lambda_{min}\) (the lowest values among all the wavelengths) Hereafter: \(\Delta x = \Delta y = \Delta z = 45\) nm. The time step \(\Delta t\) must fulfill the condition: \(\Delta t \ll \frac{\Delta z}{c}\). Finally the fields inputs (pump and signal) are known as the ‘source issue’. Since no perfect source is available, we choose an \(xy\) plane at \(z_{source} = 6\Delta z\) in which we define a polarized electric field. \(\mathbf{E}_{source} = E_{0}(xy) \mathbf{e}_{z}\). This source impinges on the diaphragm so that a Gaussian beam enters the waveguide itself at \(z = 11\Delta z\). The total waveguide length is 15\(\Delta z = 0.665\) \(\mu m\) and the number of time steps is 25000, which amounts to a total simulated time of 0.3 10^{-12} \(s\).

**Rate equations**

In this section, we detail the ADE part of the method which describes the time population dynamics of Si-ng and Nd^{3+} levels with the following rate equations.

**Silicon nanoclusters**

We consider both radiative \(r\) and non radiative \(nr\) transitions. The optical pumping power (in m^{-3}) writes:

$$\frac{1}{\hbar \omega_{p}} \frac{dP_{p}(t)}{dt}$$

The energy transfer between Si-ng and
Rare earth ions Nd$^{3+}$

A five level scheme is adopted for the Nd$^{3+}$ ion in Figure 2 [9,10].

We consider three radiative transitions ($4I_{3/2} \rightarrow 4I_{13/2}$, $\lambda_{20} = 945$ nm; $4I_{3/2} \rightarrow 4I_{11/2}$, $\lambda_{21} = 1064$ nm; and $4F_{3/2} \rightarrow 4I_{13/2}$, $\lambda_{34} = 1340$ nm) and three non radiative transitions ($4F_{5/2} \rightarrow 4F_{3/2}$ ($N_3 \rightarrow N_2$) and $4I_{11/2} \rightarrow 4I_{9/2}$) and $4I_{13/2} \rightarrow 4I_{11/2}$ ($N_4 \rightarrow N_1$)).

The terms $\frac{1}{\hbar \omega_{21}} E(t) \frac{dP_{21}(t)}{dt}$ and $\frac{1}{\hbar \omega_{20}} E(t) \frac{dP_{20}(t)}{dt}$ correspond to the stimulated transitions $2 \rightarrow 1$, $2 \rightarrow 0$ and $2 \rightarrow 4$. The terms $\frac{N_2(t)}{\tau_{21} |_{nr}}$ and $\frac{N_2(t)}{\tau_{24} |_{nr}}$ correspond to the spontaneous transitions $2 \rightarrow 1$, $2 \rightarrow 0$ and $2 \rightarrow 4$.

The associated rate equations read:

$$\frac{dN_3(t)}{dt} = \frac{N_3(t)}{\tau_{32} |_{nr}} + KN_{Si}^s(t)N_0(t).$$

Application to rib-loaded waveguide

In table 1, we collect the simulation parameters taken into account for the transitions. The lifetimes correspond to the experimental ones divided by the scaling factor $10^5$.

The transfer coefficient $K$ estimated to $\sim 10^{-20}$ m$^3$ s$^{-1}$ [11] has also been scaled with the same factor $10^5$. The amplitudes of the input pumping and signal electric fields have been taken equal to $E_{pump} = 10^7$ V m$^{-1}$ and $E_{signal} = 100$ V m$^{-1}$.

After the time Fourier transform of both $E$ and $H$ fields, we deduce the $z$ component of the pump ($P_{pump}^z$) and signal ($P_{signal}^z$) Poynting vectors (in W m$^{-2}$).

Three Si-ng concentrations have been investigated ($N_{ij} = 10^{25}$, $10^{24}$ and $10^{23}$ m$^{-3}$). In the initial states, only the ground level is populated. The corresponding $(xz)$ maps ($P_{pump}^z$) are plotted in Figures 3, 4 and 5.

In these figures, the different calculation box zones may be recognized: 1) The Perfectly Matched Layer (PML) which lies in the area from the left hand side between $z = 0$ nm and $z = 180$ nm, and from the

</table>
righthand side between \( z = 890 \text{ nm} \) and \( z = 1000 \text{ nm} \), ii) the plane containing the electromagnetic field source at \( z \approx 300 \text{ nm} \), iii) the FDTD zone which is located at about 180 nm from border of plot, the Gaussian beam impinging in the waveguide at \( z \approx 500 \text{ nm} \) and the intensity propagating in waveguide from \( z \approx 500 \text{ nm} \) to \( z \approx 900 \text{ nm} \).

On the basis of the parameters taken from experiments, these plots evidence the fact that for Si-ng concentrations above \( 10^{24} \text{ m}^{-3} \), the pumping wave does not reach the end of the waveguide. This concentration threshold corresponds to high experimental values [12], and is above the lower values leading to minimal optical losses [1].

In order to reduce the computing time, in addition to the scaling method, we start the calculations with Si-ng levels already populated at the maximum inversion rate, \( N_{Si}^{\ast} = N_{Si}^{*} = 5 \times 10^{22} \text{ m}^{-3} \). Hence, for a given total Si-ng concentration of \( 10^{23} \text{ m}^{-3} \), this result (Figure 6) can be compared to the preceding one where \( N_{Si} = 10^{23} \text{ m}^{-3} \) and \( N_{Si}^{\ast} = 0 \) (Figure 5). The propagation of the pump power within the waveguide seems to be similarly attenuated in both cases. The main difference occurs in the \( N_{3} \) level concentration which is directly populated from the excited \( N_{Si}^{\ast} \) level. In case of maximum inversion rate, the stationary regime is reached and the concentration becomes equal to \( N_{3} = \tau_{32}.K.N_{Si}^{\ast}.N_{0} \approx 1.1 \times 10^{18} \text{ m}^{-3} \). In case of \( N_{Si} = 10^{23} \text{ m}^{-3} \) and \( N_{Si}^{\ast} = 0 \) starting...
concentration, the $N_s$ concentration does not reach a stationary regime and stays below several $10^{17}$ m$^{-3}$.

**Conclusion**

We have investigated by means of ADE-FDTD method the electromagnetic field propagation in rib-loaded waveguides constituted of an active layer of Nd$^{3+}$ doped silicon rich silica stacked between pure silica bottom cladding and rib. This numerical method treats Nd$^{3+}$ and Si-n$g$ levels rate equations (ADE) coupled to the Maxwell equations (FDTD). The extremely different specific times involved in the ADE (levels lifetimes $\approx 10$ µs) and in FDTD (electromagnetic wave periods $\approx 10^{-15}$ s) have required the use of the scaling time method which allows reasonable computing time: the number of time iterations has been reduced by six orders of magnitude. In addition to this method, we have proposed to start the calculations with steady state Si-n$g$ ground and excited populations. The numerical computation has been performed for several Si-n$g$ concentrations. Therefore we can infer that the pumping wave propagation ($\lambda_{pump} = 488$ nm) is possible for $[\text{Si-n}g] \leq 10^{24}$ m$^{-3}$ in agreement with experimental loss measurements. The upper Nd$^{3+}$ level reaches its stationary value predicted with the analytical solution of the steady state rate equations.
