Minimal geodesics along volume preserving maps, through semi-discrete optimal transport

Quentin Mérigot∗†  Jean-Marie Mirebeau∗‡

August 30, 2016

Abstract

We introduce a numerical method for extracting minimal geodesics along the group of volume preserving maps, equipped with the $L^2$ metric, which as observed by Arnold [Arn66] solve the Euler equations of inviscid incompressible fluids. The method relies on the generalized polar decomposition of Brenier [Bre91], numerically implemented through semi-discrete optimal transport. It is robust enough to extract non-classical, multi-valued solutions of Euler’s equations, for which the flow dimension - defined as the quantization dimension of Brenier’s generalized flow - is higher than the domain dimension, a striking and unavoidable consequence of this model [Shn94]. Our convergence results encompass this generalized model, and our numerical experiments illustrate it for the first time in two space dimensions.

1 Introduction

The motion of an inviscid incompressible fluid, moving in a compact domain $X \subseteq \mathbb{R}^d$, is described by the Euler equations [Eul65]

$$\partial_t v + (v \cdot \nabla)v = -\nabla p \quad \text{div } v = 0,$$  \hspace{1cm} (1)

coupled with the impervious boundary condition $v \cdot n = 0$ on $\partial \Omega$. Here $v$ denotes the fluid velocity, and $p$ the pressure acts as a Lagrange multiplier for the incompressibility constraint. As observed by Arnold [Arn66], Euler equations (1) yield in Lagrangian coordinates the geodesic equations along the group $\text{SDiff}$ of diffeomorphisms of $X$ with unit jacobian, equipped with the $L^2$ metric. Indeed, let $s : [0, 1] \to \text{SDiff}$ be a smooth time dependent family of diffeomorphisms of $X$, describing the evolution over time of the position of the fluid particles. The position of the particle emanating from $x$ at time $t$ will be denoted indifferently $s_t(x)$ or $s(t, x)$, while the diffeomorphism at time $t$ is denoted $s(t)$ or $s_t$. The Eulerian velocity $v$ and acceleration $a$ of the fluid particles are given by $v(t, s(t, x)) = \partial_t s(t, x)$ and $a(t, s(t, x)) = \partial_{tt} s(t, x)$. The jacobian constraint $\det \nabla s = 1$ yields $\text{div } v = 0$, whereas the equation of geodesics on $\text{SDiff}$ merely states that acceleration is a gradient, $a(t, x) = -\nabla p(t, x)$, which is equivalent to (1). This formalism leads to two natural problems for Euler equations:

• The Cauchy problem, forward in time: given the initial position and velocity of the fluid particles, find their subsequent positions at all positive times. This amounts to computing the exponential map on the lie group $\text{SDiff}$.

The boundary value problem: given some observed initial and final positions of the fluid particles, find their intermediate states. This amounts to computing a minimizing geodesic on SDiff.

This manuscript is devoted to the boundary value problem only. More precisely, consider an inviscid incompressible fluid flowing during the time interval $[0, 1]$, and a map $s^* : X \to X$ giving the final position $s^*(x)$ of each fluid particle initially at position $x \in X$. In this paper, we introduce a new numerical scheme for finding a minimizing geodesic joining the initial configuration $s_* = \text{Id}$ to the final one $s^*$.

$$\begin{align*}
\text{minimize} & \int_0^1 \|\dot{s}(t)\|^2 dt, \\
\text{subject to} & \forall t \in [0, 1], \ s(t) \in \mathbb{S}, \\
& s(0) = s_*, \ s(1) = s^*. 
\end{align*}$$

We denote by $\mathbb{S} \subseteq L^2(X, \mathbb{R}^d)$ the space of maps preserving the Lebesgue measure on $X$, which in dimension $d \geq 3$ is the closure of SDiff. More formally, we let $\text{Leb}$ denote the Lebesgue measure on $X$, rescaled so as to be a probability measure, and we let $f \# \mu$ denote the push-forward of a measure $\mu$ by a measurable map $f$, defined by $f \# \mu(A) := \mu(f^{-1}(A))$. Then the space $\mathbb{S}$ is the collection of measurable maps $s : X \to X$ obeying $s \# \text{Leb} = \text{Leb}$.

The motivation for this first relaxation — replacing SDiff with the closed subset $\mathbb{S}$ of $L^2$ — is that the optimized functional in (2) does not penalize the spatial derivatives of $s$, which are involved in the unit jacobian constraint defining SDiff. Despite this relaxation, the optimization problem (2) needs not have a minimizer in $s \in H^1((0, 1), \mathbb{S})$ in dimension $d \geq 3$ [Shn94], and minimizing sequences $(s_n)_{n \in \mathbb{N}}$ may instead display oscillations reminiscent of an homogenization phenomenon. A second relaxation is therefore necessary, see [FD12] for a review.

**Generalized flows** Brenier introduced in [Bre89] a second relaxation of the minimizing geodesic problem (2) based on generalized flows, which allow particles to split and their paths to cross. This surprising behavior is an unavoidable consequence of the lack of viscosity in Euler’s equations, which amounts to an infinite Reynolds number. Generalized flows are also relevant in dimension $d \in \{1, 2\}$ if the underlying physical model actually involves a three dimensional domain $X \times [0, \varepsilon]^{3-d}$ in which one neglects the fluid acceleration in the extra dimensions [Bre08]. Consider the space of continuous paths (of fluid particles)

$$\Omega := C^0([0, 1], X).$$

A *generalized flow*, in Brenier’s sense [Bre89], is a probability measure $\mu$ over the space $\Omega$ of paths. We denote by $e_t(\omega) := \omega(t)$ the evaluation map at time $t \in [0, 1]$. Given a generalized flow $\mu \in \text{Prob}(\Omega)$, the push-forward map $e_t \# \mu$ can be understood as the distribution of particles at time $t$ under the flow. The generalized flow is *incompressible* if for every time $t \in [0, 1]$, $e_t \# \mu$ coincides with the uniform probability measure on the domain $X$. Rescaling the domain if necessary we assume that $X$ has unit area, so that the uniform probability measure Leb is simply the restriction of the Lebesgue measure to $X$.

The use of generalized flows turns the highly non-linear incompressibility constraint $s(t) \in \mathbb{S}$ into a linear constraint $e_t \# \mu = \text{Leb}$. Note the similarity with Kantorovich’s linearization of the non-linear mass preservation constraint in Monge’s optimal transport problem. This idea leads to a convex relaxation of the minimizing geodesic distance problem (2), linearizing both
Figure 1: The motion of inviscid incompressible fluids admits three formulations, either (I) Eulerian based on the local speed $v : [0, 1] \times X \to \mathbb{R}^d$, (II) Lagrangian based on diffeomorphisms $s(t, \cdot)$ which integrate the speed: $\partial_t s(t, x) = v(t, s(t, x))$, or (III) relaxed as a superposition of individual particles paths $\omega \in \Omega$, weighted by a measure $\mu$.

the objective and the constraints, and for which the existence of a minimizer is guaranteed:

$$d^2(s_*, s^*) := \min_{\mu \in \text{Prob}(\Omega)} \int_{\Omega} A(\omega) d\mu(\omega),$$

where $A(\omega) = \int_0^1 |\dot{\omega}(t)|^2 dt$

and subject to

$$\forall t \in [0, 1], e_t \# \mu = \text{Leb},$$

$$(e_0, e_1) \# \mu = (s_*, s^*) \# \text{Leb}.$$ (3)

As explained above, the first constraint in (3) expresses the incompressibility of the generalized flow. The second constraint $(e_0, e_1) \# \mu = (s_*, s^*) \# \text{Leb}$ rephrases the prescription of the end-points $(s(0) = s_*$ and $s(1) = s^*)$ in the minimizing geodesic problem (2) by imposing a coupling between particle positions at initial and final times. This second constraint can equivalently be phrased in terms of test functions: for every $f \in C^0(X \times X, \mathbb{R})$ one has

$$\int_{\Omega} f(\omega(0), \omega(1)) d\mu(\omega) = \int_X f(s_*(x), s^*(x)) dx.$$ (4)

In other words, $\omega(1) = s^*(s_*^{-1}(\omega(0)))$ for $\mu$-almost any particle path $\omega \in \Omega$. Any classical flow $s \in H^1([0, 1], \mathbb{S})$ can be represented by a generalized flow $\mu_s$, supported on the paths $\omega_x : t \mapsto s(t, x)$, weighted by the Lebesgue measure on $x \in X$. In this case, if $F : \Omega \to \mathbb{R}$ is a bounded and continuous functional (or a lower-semi-continuous non-negative functional such as $A$) one has

$$\int_{\Omega} F(\omega) d\mu_s(\omega) = \int_{\Omega} F(\omega_x) dx.$$ (4)

In particular,

$$\int_{\Omega} A(\omega) d\mu_s(\omega) = \int_X \int_0^1 |\dot{s}(t, x)|^2 dt dx = \int_0^1 \|\dot{s}(t)\|^2 dt.$$ (5)

In other words, the $\mu$-average of the particles paths energy, is the time average of the fluid kinetic energy. Note that in this paper, $\|\cdot\|$ stands for the $L^2(X, \mathbb{R}^d)$ norm, and $|\cdot|$ for the Euclidean norm on $\mathbb{R}^d$. Our discretization truly solves Brenier’s relaxation (3), rather than Arnold’s formulation (2), and convergence is established in this relaxed setting.

**Pressure.** The incompressibility constraint in (3) gives rise to a Lagrange multiplier, called the pressure and which generalises the field $p$ in (1). Pressure turns out to be the unique maximizer
to a concave optimization problem dual to (3), see [Bre93]. Note that, in contrast, the primal problem (3) may have several minimizers — up to the notable exception [BFS09] of smooth flows in dimension $d = 1$. The pressure is a classical function $p \in L^2_{\text{loc}}([0, 1], \text{BV}(X))$, at least when the domain $X$ is a $d$-dimensional torus [AF07]. This regularity is sufficient to show that any solution $s$ to (2) (resp. $\mu$-almost any path $\omega$, for any solution $\mu$ to (3)) satisfies

$$
\partial_{tt}s(t, x) = -\nabla p(t, s(t, x)), \quad \text{resp.} \quad \ddot{\omega}(t) = -\nabla p(t, \omega(t)).
$$

This implies that the support of $\mu$ is contained in the space of solutions to a second-order Ordinary Differential Equation (ODE), a fact that we will use later in our convergence estimates. In other words, fluid particles move by inertia, only deflected by the force of pressure. Assume that the Hessian of the pressure is sufficiently small, namely that

$$
\forall t \in [0, 1], \forall x \in X, \nabla^2 p(t, x) \prec \pi^2 \text{Id}
$$

in the sense of symmetric matrices

1. Then using the path dynamics equation (6) Brenier [Bre89] proved that the relaxed problem (3) admits a unique minimizer $\mu \in \text{Prob}(\Omega)$, which is deterministic. In other word, the generalized flow $\mu$ stems as in (4) from a possibly non-smooth but otherwise classical minimizer $s \in H^1([0, 1], \mathcal{S})$ of (2). Inequality (7) is sharp, and several families of examples are known for which uniqueness and/or determinism are lost precisely when the threshold (7) is passed. We present in §5 the first numerical illustration of this phenomenon.

1.1 Numerical scheme

We introduce a new discretization for the relaxation (3) of the shortest path formulation (2) of Euler equations (1). Our approach is numerically tractable in dimension 2, and is the first to illustrate the transition between classical and generalized solutions occurring at the threshold (7) on the pressure regularity.

For that purpose we need to introduce some notation. As before, we denote $\text{Leb}$ the Lebesgue measure restricted to the domain $X$, which by assumption is a probability measure on $X$. Denote $\mathcal{M} := L^2(X, \mathbb{R}^d)$, and recall that $\mathcal{S} \subseteq \mathcal{M}$ is the collection of maps $s \in \mathcal{M}$ preserving the Lebesgue measure on the domain $X$, i.e. $s\# \text{Leb} = \text{Leb}$. For every $N \in \mathbb{N}$, we let $\mathcal{P}_N$ be a partition of $X$ into $N$ regions of equal area $1/N$, with respect to the Lebesgue measure, and with diameter $\leq C_\rho N^{-\frac{1}{2}}$. Finally, we let $\mathcal{M}_N \subseteq \mathcal{M}$ be the $N$-dimensional subspace of functions which are piecewise constant over this partition. Given two measure-preserving maps $s_*, s^* \in \mathcal{S}$,

1We write $A \prec B$, where $A$ and $B$ are two symmetric matrices, if $B - A$ is positive definite.
properties of the set 
the numerical implementation strategy, and the other results crucially rely on the specific subspaces of the problem. It makes sense to consider (8) and (9) whenever one attempts to approximate a shortest path between the maps \( m_i \) and the set \( \mathcal{S} \) of measure-preserving maps. The discrete optimization problem we consider is then

\[
\mathcal{E}(T, N, \lambda; m) := \min_{m \in M_N^{T+1}} \mathcal{E}(T, N, \lambda; m)
\]

(9)

The problem (9), considered as a function of \( m \in M_N^{T+1} \), is an \( (T+1)d \)-dimensional optimization problem. It makes sense to consider (8) and (9) whenever one attempts to approximate a shortest path joining two points \( s_s, s^* \) of a subset \( \mathcal{S} \) of a Hilbert space \( \mathcal{H} \), internally approximated by subspaces \( (M_N)_N \geq 0 \). Our first result Proposition 1.1 uses no additional assumptions. In contrast, the numerical implementation strategy, and the other results crucially rely on the specific properties of the set \( \mathcal{S} \) of measure-preserving maps.

The key properties of the functional (8) follow from those of the squared distance function \( d^2_{\mathcal{S}} \), which are established in Proposition 5.1. It is continuously differentiable on an open dense set. However it is non-convex (in fact semi-concave) due to the non-convexity of the set \( \mathcal{S} \), forbidding us to guarantee that the global minimum of (8) is found by our numerical solver. Nonetheless, our numerical experiments show that quasi-Newton methods give convincing results, see §5.

Distance to \( \mathcal{S} \) and semi-discrete optimal transport. Before entering the analysis of (8), we want to emphasize that the inner-subproblems, namely the computation of the squared distances \( d^2_{\mathcal{S}}(m_i) \), are numerically tractable thanks to two main ingredients: Brenier’s polar factorization [Bre91], and semi-discrete optimal transport. Brenier’s polar factorization theorem asserts that the distance between any \( m \in \mathcal{M} \) and the set \( \mathcal{S} \) of measure-preserving maps equals the cost of transporting the image measure \( m \# \text{Leb} \) back to the Lebesgue measure, namely

\[
d^2_{\mathcal{S}}(m) = \inf_{s \in \mathcal{S}} \| m - s \|^2 = W^2_2(m \# \text{Leb}, \text{Leb}),
\]

(10)

where \( W_2 \) is the Wasserstein distance for the quadratic transport cost. Given any \( m \in \mathcal{M} \), the pushforward measure \( m \# \text{Leb} \) is the sum of \( N \) Dirac measures of mass \( 1/N \), located at the \( N \) values of the piecewise constant map \( m \) on the partition \( \mathcal{P}_N \). Computing (10) therefore amounts to the computation of the Wasserstein distance between a finitely supported measure and the Lebesgue measure, a special instance of a problem called semi-discrete optimal transport. Efficient computational methods for this problem have been proposed [AHA98, Mer11, Lév14], relying on Kantorovich duality and on tools from computational geometry. Let \( \eta \) be the uniform probability measure over a finite set \( Y \subseteq \mathbb{R}^d \) with cardinal \( N \). Kantorovich duality asserts that

\[
W_2^2(\eta, \text{Leb}) = \sup_{f: \mathcal{X} \to \mathbb{R}, g: \mathcal{Y} \to \mathbb{R}} \int X f(x) d\text{Leb}(x) + \int Y g(y) d\eta(y).
\]
For any fixed \( g : Y \to \mathbb{R} \) the largest \( f : X \to \mathbb{R} \) obeying the constraint is given by

\[
    f(x) := \min_{y \in Y} \|x - y\|^2 - g(y).
\]

This function is piecewise quadratic over a partition \( (\mathrm{Lag}_y(g))_{y \in Y} \) of \( X \) into convex polyhedra

\[
    \mathrm{Lag}_y(g) := \{ x \in X \mid \forall z \in Y, \|x - y\|^2 - g(y) \leq \|x - z\|^2 - g(z) \}.
\]

Eliminating the optimization variable \( f \), Kantorovich duality reads

\[
    W_2^2(\eta, \text{Leb}) = \sup_{g : Y \to \mathbb{R}} \sum_{y \in Y} \int_{\mathrm{Lag}_y(g)} (\|x - y\|^2 - g(y)) \, dx + \frac{1}{N} \sum_{y \in Y} g(y). \tag{11}
\]

This partition of \( X \) is called the Laguerre diagram of \( (Y, g) \) in computational geometry and can be computed in near-linear time in \( \mathbb{R}^2 \) using existing software [cga]. Specifically, we use the 2D regular triangulations package in CGAL [Yvi13]. The maximization problem (11) is an unconstrained, concave and twice continuously differentiable maximization problem, which is efficiently solved via Newton or quasi-Newton methods. Semi-discrete optimal transport has become a reliable and efficient building block for PDE discretizations [BCMO14].

As discussed above, the chosen discretization of the Euler equations intrinsically leads to an optimal transport problem of semi-discrete type - from a finite collection of Diracs playing the role of fluid particles to the standard Lebesgue measure - hence our choice of discretization (11). A variety of alternative approaches have been developed for other instances of computational optimal transport, based for instance on a pressure-less fluid model [BBG02, PPO13], monotone discretizations of Monge-Ampère equation [BFO14, BCM14], regularization via entropy penalization [BCC+15, CPR15], or adaptive strategies for the linear programming discretization [OR15, Sch15].

1.2 Main results

Our results on the proposed discretization (8) are split into two parts. A convergence analysis first shows how to construct discrete generalized flows out of minimizers of \( \mathcal{E}(T, N, \lambda) \), supported on finitely many piecewise linear paths and which converge to a solution \( \mu \in \Pr(\Omega) \) of (3). This analysis requires upper bounds on the discrete energies \( \mathcal{E}(T, N, \lambda) \), which are established in a second part and under adequate a-priori assumptions on the continuous solution. Importantly, two sets of assumptions are considered, encompassing the favorable case where a classical solution to Arnold’s formulation (2) exists, and the general case where only Brenier’s relaxation (3) is well posed.

**Convergence analysis.** We present two results establishing the convergence of the discretized problem (9) minimizers towards solutions of (3) as the number of timesteps \( T \) grows to infinity. The first proposition shows that one can build short chains of incompressible maps out of minimizers of (9). It involves the quantity

\[
    \mathcal{E}'(T, N, \lambda; m) := (1 + 4T/\lambda)\mathcal{E}(T, N, \lambda; m). \tag{12}
\]
Proposition 1.1. Let $m = (m_i)_{i=0}^T \in M_N^{T+1}$ and let $(s_i)^T_{i=0}$ be the chain of incompressible maps defined by: $s_0 = s_*$, $s_T = s^*$, and $s_i$ is a projection of $m_i$ onto $\mathbb{S}$ for all $1 \leq i < T$. Then

$$T \sum_{0 \leq i < T} \|s_{i+1} - s_i\|^2 \leq \mathcal{E}'(T, N, \lambda; m).$$

Unfortunately, such discrete chains of incompressible maps need not converge as $T \to \infty$ to a continuous path $s : [0, 1] \to \mathbb{S}$, due to the lack of compactness of $\mathbb{S}$. Note also that the interpolates $(1 - \delta)s_i + \delta s_{i+1}, 0 \leq \delta \leq 1, 0 \leq i \leq T$, need not belong to the non-convex set $\mathbb{S}$.

The next proposition establishes, under condition, convergence towards a solution of (3) in the sense of generalized flows, a framework which enjoys the desired convexity and compactness properties. In order to state this result, we associate to each $m = (m_i)_{i=0}^T$ in $M_N^{T+1}$ a generalized flow $\mu_m \in \text{Prob}(\Omega)$ uniformly supported on $N$ paths. For every $j \in \{1, \ldots, N\}$, we denote $m_j^i$ the (constant) value of $m_i$ on the $j$-th region of the partition $\mathcal{P}_N$ of $X$ and we define a path $\omega_j$ by interpolating linearly between these points, that is

$$\forall 0 \leq i \leq N, \omega_j(i/t) = m_j^i.$$  

The construction of these paths is illustrated in Figure 3. Finally $\mu_m \in \text{Prob}(\Omega)$ is the uniform probability measure over the finite set of paths $\{\omega_1, \ldots, \omega_N\} \subseteq \Omega$. We present in §2.2 a reformulation of the discrete energy (8) based on the generalized flow $\mu_m \in \text{Prob}(\Omega)$, which mimics Brenier's linear relaxation (3) of Euler’s equations.

Proposition 1.2. Assume that $\mathcal{E}'(T_k, N_k, \lambda_k; m_k) \to D_*$ and $T_k, N_k, \lambda_k \to +\infty$ as $k \to \infty$. Then a subsequence of the generalized flows $\mu_k$ associated to $m_k$ weak-* converges to a flow $\mu \in \text{Prob}(\Omega)$ satisfying $\int_{\Omega} A d\mu \leq D_*$ and obeying the constraints of (3).

Corollary 1.3. Under the assumptions of Proposition 1.2, one has $D_* \geq d(s_*, s^*)$. If equality holds, then the limit $\mu$ is a solution to (3).

Interestingly, the proof of Proposition 1.2 presented §2.2 relies on a reinterpretation of the discretization (8) of Arnold’s geodesic formulation (2) of Euler equations, which turns out to be the natural discretization of Brenier’s relaxation (3) as well.
Figure 4: Illustration of Remark 1.6. The set $S$ is the red curve and the set $S_N$ is composed of the four large dots. The discretized geodesics is displayed as a dotted line. On the left, the penalization parameter $\lambda$ is too small and the discretized geodesics takes “shortcuts”, while on the right $\lambda$ is too large, leading to overfitting.

**Upper bounds on the discrete energy.** Our main theorem establishes upper bounds on the discrete energies $E(N, T, \lambda)$, for adequate values of the parameters, as required by the convergence result Proposition 1.2. It relies on a-priori assumptions on the structure of solutions to the continuous problem. The “relaxed” part of this result addresses the general case, based on Brenier’s linear relaxation (3) of the Euler equations, and only requires on an assumption on the pressure regularity. The “classical” part provides a faster convergence rate under the assumption that Arnold’s geodesic formulation (2) admits a minimizer $s : [0, 1] \times X \to X$, of suitable regularity. At a given time $t$, the fluid velocity $s(t, x)$ is uniquely determined by position $x \in X$ in the classical case, whereas in the relaxed case it is a probabilistic superposition $\bar{\omega}(t)$ of velocities, weighted by the generalized flow solution $\mu \in \text{Prob}(\Omega)$ conditional to $\omega(t) = x$; this is in a sense reminiscent of non-classical, quantum mechanics, hence the choice of adjective.

Recall that the classical (2) and relaxed (3) distances are automatically equal in dimension $d \geq 3$, and that the pressure field gradient $\nabla p$ is uniquely determined by the boundary values $s_*, s^*$.

**Theorem 1.4.** Let $s_*, s^* \in S$, let $T, N \in \mathbb{N}$, and $\lambda \geq 0$. The relaxed geodesic distance (3) and the discretized minimum (9) satisfy

$$E(T, N, \lambda) \leq d(s_*, s^*) + O(Th_N^2 \lambda),$$

- (Classical estimate) with $h_N = N^{-\frac{2}{d}}$ assuming that the classical geodesic distance (2) equals the relaxed distance (3), and admits a minimizer with regularity $s \in L^\infty([0, 1], H^1(X))$.
- (Relaxed estimate) with $h_N = N^{-\frac{1}{d}}$ (resp. $N^{-\frac{1}{d}}\sqrt{\ln N}$ if $d = 1$), if the pressure field gradient $\nabla p$ is Lipschitz on $[0, 1] \times X$, and the boundary data $s_*^{-1}, s^*$ are Lipschitz on $X$.

**Remark 1.5 (Optimal choice of the parameter $\lambda$).** Since the natural quantity occurring in the convergence analysis is $E'(T, N, \lambda)$, see (12), it is natural to choose $\lambda = h^{-1}_N = N^\frac{1}{d}$ so that by Theorem 1.4

$$E'(T, N, \lambda) \leq d^2(s_*, s^*) + O(T/\lambda + Th_N^2 \lambda) \leq d^2(s_*, s^*) + O(TN^{-\frac{1}{d}}).$$

From this point, choosing $N, T \to \infty$ in such way that $TN^{-\frac{1}{d}} \to 0$, will fulfill the assumptions required by Proposition 1.2 for convergence.

**Remark 1.6 (Finite-dimensional analogy for the choice of $\lambda$).** Consider a finite $d$-dimensional manifold $S$ embedded in a Hilbert space $M$, whose minimising geodesics one wishes to approximate. The minimising geodesics between two points $s_*, s^* \in S$ can be approximated by minimisers of the energy

$$(m_0, \ldots, m_T) \in M^{T+1} \mapsto T \sum_{0 \leq i < T} \|m_{i+1} - m_i\|^2 + \lambda \left(\|m_0 - s_*\| + \|m_T - s^*\| + \sum_{1 \leq i < T} d_{S_N}(m_i)\right),$$

for
where \( S_N \) is a sampling of the manifold \( S \) with \( N \) points. The choice of the optimal \( \lambda \) in term of convergence speed depends on the dimension of the manifold \( S \) and on the number of points \( N \). Figure 4 illustrates that if \( \lambda \) is too small, the discrete geodesics takes “shortcuts”, while if \( \lambda \) is too large it forms clusters around points in the discretization \( S_N \). Note also that, for a fixed \( N \) and \( \lambda \to \infty \), the optimization problem becomes combinatorial.

Establishing the upper bounds of Theorem 1.4 requires one to construct, for each choice of \( N, T \), a candidate \( m \in \mathbb{M}^{T+1}_N \) for the discrete problems (9) from a minimizer \( \mu \in \text{Prob}(\Omega) \) of the continuous problem (3). To do so, we approximate the probability measure \( \mu \) by a measure \( \mu_N \) uniformly supported over \( N \) paths. This amounts to solving a quantization problem \([GG92]\) in the infinite-dimensional space \( \Omega \). Fortunately, the optimal speed of convergence of \( \mu_N \) towards \( \mu \) can be bounded in terms of the box dimension \( D \) of the support of \( \mu \) (see Definition 4.1). This explains why the decay rate \( h_N = N^{−\frac{1}{D}} \) in Theorem 1.4 depends, through the constant \( D \), on the structure of the problem solution \( \mu \).

When the generalized flow \( \mu \) is induced by a classical solution, as in (4), the particle trajectories are determined by their initial position \( x \in X \subseteq \mathbb{R}^d \), so that \( \mu \) is supported on a \( d \)-dimensional manifold, implying \( D = d \). In the relaxed estimate however, the trajectories particles obey a second order ordinary differential equation (6) and are thus determined by their initial position and velocity \((x, v) \in X \times \mathbb{R}^d \subseteq \mathbb{R}^{2d} \) provided Picard-Lindelof/Cauchy-Lipschitz’s theorem applies \([CL55]\). The quantization dimension of the generalized flow is thus \( 2d \) in the worst case, but intermediate dimensions \( d < D < 2d \) are also common, see §5.

Outline. Propositions 1.1 and 1.2 are proved in §2. Theorem 1.4 is established in §3 (Classical estimate) and in §4 (Relaxed estimate). Numerical experiments are presented §5.

Remark 1.7 (Monge-Ampere gravitation). Some models of reconstruction of the early universe \([Bre11]\) involve actions of a form closely related to our discrete energy functional (9), for the parameter value \( \lambda = 2 \):

\[
\int_0^1 \left( \frac{1}{2} \| \dot{\mu}(t) \|^2 + \inf_{s \in S} \| m(t) - s \|^2 \right) dt.
\]

2 Convergence analysis

We prove Proposition 1.1 in §2.1 and Proposition 1.2 in §2.2 on the length of chains of incompressible maps, and the convergence of generalized flows respectively.

2.1 Length of a chain of incompressible maps

The announced Proposition 1.1 immediately follows from Lemma 2.1 below. It relies on a following identity, valid for any elements \( a, b \) of a Hilbert space, and any \( \varepsilon > 0 \):

\[
(1 + \varepsilon)^{-1} \| a + b \|^2 \leq \| a \|^2 + \varepsilon^{-1} \| b \|^2.
\]  

Indeed subtracting the LHS to the RHS of (13) we obtain \((1 + \varepsilon)^{-1} \| \varepsilon^{\frac{1}{2}} a - \varepsilon^{-\frac{1}{2}} b \|^2 \geq 0 \).

Lemma 2.1. For any \( T \in \mathbb{N}^* \), any penalization \( \lambda > 0 \), and any \((m, s) \in (\mathbb{M} \times S)^{T+1} \) one has

\[
T \sum_{0 \leq i < T} \| s_{i+1} - s_i \|^2 \leq (1 + 4T/\lambda) \left[ T \sum_{0 \leq i < T} \| m_{i+1} - m_i \|^2 + \lambda \sum_{0 \leq i < T} \| m_i - s_i \|^2 \right].
\]
Proof. Let $0 \leq i < T$. Choosing $a := s_{i+1} - s_i$, and $b := m_{i+1} - m_i - a$, we obtain
\[
(1 + \varepsilon)^{-1}||m_{i+1} - m_i||^2 \leq ||s_{i+1} - s_i||^2 + \varepsilon^{-1}||s_i - m_i - (s_{i+1} - m_{i+1})||^2 \\
\leq ||s_{i+1} - s_i||^2 + 2\varepsilon^{-1}(||s_i - m_i||^2 + ||s_{i+1} - m_{i+1}||^2).
\]
Summing over $0 \leq i < T$ yields
\[
(1 + \varepsilon)^{-1} \sum_{0 \leq i < T} ||m_{i+1} - m_i||^2 \leq \sum_{0 \leq i < T} ||s_{i+1} - s_i||^2 + 2\varepsilon^{-1} \sum_{0 \leq i < T} \alpha_i||s_i - m_i||^2,
\]
with $\alpha_0 = \alpha_T = 1$, $\alpha_i = 2$ otherwise. Choosing $\varepsilon = 4T/\lambda$ concludes the proof. \qed

2.2 Convergence towards generalized solutions

This subsection is devoted to the proof of Proposition 1.2. The discrete optimization problem \((9)\) is inspired by Arnold’s formulation \((2)\) of Euler equations as a minimizing geodesic problem over \(S\). Our first lemma shows that, in the equivalent form \((24)\), it could as well be regarded as a discretization of Brenier’s relaxation \((3)\). The terms \(W_2^2(e_t \# \mu_m, \text{Leb})\), where \(m \in \mathbb{M}_N^{T+1}\) and \(\mu_m\) is the induced generalized flow, can indeed be regarded as penalizations of the relaxed incompressibility constraint \(e_t \# \mu = \text{Leb}\) in \((3)\). The other term \(W_2^2((e_0, e_1) \# \mu_m, (s_*, s^*) \# \text{Leb})\) enforces the proximity between the two couplings \((e_0, e_1) \# \mu_m\) and \((s_*, s^*) \# \text{Leb}\) on \(X^2\) as required in \((3)\).

Lemma 2.2. Let \(m = (m_i)_{i=0}^T \in \mathbb{M}_N^{T+1}\) and \(\mu_m \in \text{Prob}(\omega)\) be the induced generalized flow. Then \(\mathcal{E}(T, N, \lambda; m)\) equals
\[
\int_{\Omega} \mathcal{A}(\omega) d\mu_m(\omega) + \lambda \left( \int_X |m_0(x) - s_*(x)|^2 + |m_T(x) - s^*(x)|^2 dx + \sum_{1 \leq i < T} W_2^2(e_i \# \mu_m, \text{Leb}) \right). \quad (15)
\]
In addition,
\[
W_2^2((e_0, e_1) \# \mu_m, (s_*, s^*) \# \text{Leb}) \leq \int_X |m_0(x) - s_*(x)|^2 + |m_T(x) - s^*(x)|^2 dx. \quad (16)
\]

Proof. Mimicking \((5)\) at the discrete level, we obtain
\[
\int_{\Omega} \mathcal{A}(\omega) d\mu(\omega) = \frac{1}{N} \sum_{1 \leq j \leq N} \int_0^T |\dot{\omega}_j(t)|^2 dt = \frac{T}{N} \sum_{0 \leq i < T \leq j \leq N} ||m^j_{i+1} - m^j_i||^2 = T \sum_{0 \leq i < T} ||m_{i+1} - m_i||^2,
\]
On the other hand, Brenier’s polar factorization theorem \((10)\) yields \(W_2^2(e_t \# \mu_m, \text{Leb}) = d_2^2(m)\), which gives \((24)\).

The Wasserstein distance from \((e_0, e_1) \# \mu_m = (m_0, m_1) \# \text{Leb}\) to \((s_*, s^*) \# \text{Leb}\) appears on the LHS of \((16)\). By definition, it is indeed bounded by the cost, appearing on the RHS, of the explicit transport plan \(\pi = ((m_0, m_T), (s_*, s_*)) \# \text{Leb} \in \text{Prob}(X^2 \times X^2)\), which sends \((m_0(x), m_T(x)) \mapsto (s_*(x), s^*(x))\) for all \(x \in X\). \qed

Our next step is to estimate the average violation of incompressibility by the discrete solution.

Lemma 2.3. Let \(\mu_m\) be the generalized flow associated to some \(m \in \mathbb{M}_N^{T+1}\). Then
\[
\int_0^1 W_2^2(e_t \# \mu_m, \text{Leb}) dt \leq \frac{1}{4T^2} \mathcal{E}'(T, N, \lambda; m).
\]
Proof. Let $t \in [0, 1]$, which we write $t = (i + \alpha)/T$ with $0 \leq i < T$, $0 \leq \alpha \leq 1$. Then using (13) we obtain for any $\varepsilon > 0$,

$$W_2^2(e_t \# \mu_m, \text{Leb}) = \inf_{s \in \mathbb{S}} \|(1 - \alpha)m_i + \alpha m_{i+1} - s\|^2 \leq (1 + \varepsilon) \left( \|\alpha(m_{i+1} - m_i)\|^2 + \varepsilon^{-1} \inf_{s \in \mathbb{S}} \|m_i - s\|^2 \right)$$

Integrating over $t \in [0, 1]$, and using that either $\alpha \leq 1/2$ or $1 - \alpha \leq 1/2$, we obtain

$$\int_0^1 W_2^2(e_t \# \mu, \text{Leb}) dt \leq \frac{1 + \varepsilon}{T} \sum_{0 \leq i < T} \left( \frac{1}{4} \|m_{i+1} - m_i\|^2 + \varepsilon^{-1} \inf_{s \in \mathbb{S}} \|m_i - s\|^2 \right)$$

which is precisely the announced estimate when $\varepsilon = 4T/\lambda$. \hfill \Box

The convergence announced in Proposition 1.2 finally results from general compactness and continuity arguments.

Proof of Proposition 1.2. Let $T, N, \lambda, m, \mu$ and $D_*$ be as in the statement of Proposition 1.2. The sublevel sets of the action, such as for any $\varepsilon > 0$

$$\{\mu \in \text{Prob}(\Omega) : \int_{\Omega} A(\omega) d\mu(\omega) \leq D_* + \varepsilon\}$$

are weak-* sequentially compact by [Bre93]. Taking a subsequence if necessary, we assume that $(\mu_k)$ converges towards a $\mu_* \in \text{Prob}(\Omega)$, which thus satisfies $\int_{\Omega} A d\mu_* \leq D_* + \varepsilon$ for any $\varepsilon > 0$, hence $\int_{\Omega} A d\mu_* \leq D_*$ as announced.

The functional $F : \mu \mapsto W_2^2((e_0, e_1) \# \mu, (s, s^*) \# \text{Leb})$ is weak-* continuous on $\text{Prob}(\Omega)$. By (16) one has $F(\mu_k) \leq \frac{1}{\lambda_k} \varepsilon(T_k, N_k, \lambda_k; m_k) \to 0$ as $k \to \infty$, hence $F(\mu_*) = 0$ which implies

$$(e_0, e_1) \# \mu_* = (s, s^*) \# \text{Leb}.$$ 

Similarly, the functional $G : \mu \mapsto \int_0^1 W_2^2(e_t \# \mu, \text{Leb}) dt$ is weak-* lower semi-continuous on $\text{Prob}(\Omega)$, as follows from Fatou’s lemma and the continuity of $\mu \mapsto W_2^2(e_t \# \mu, \text{Leb})$ for any $t \in [0, 1]$. By Lemma 2.3 one has $G(\mu_k) \to 0$ as $k \to \infty$, hence $G(\mu_*) = 0$ and therefore the limit generalized flow obeys the incompressibility constraints

$$\forall t \in [0, 1], \ e_t \# \mu = \text{Leb}.$$ 

\hfill \Box

3 Classical estimate

We establish in this section the first part of our main result, Theorem 1.4. By assumption, we consider a minimizer $s$ of the shortest path problem $\Omega$, and assume that it has regularity $s \in L^\infty([0, 1], H^1(\mathbb{R}))$. Let also $T, N, \lambda$ be the discrete problem parameters.

Define $s_i := s(i/T)$ for all $0 \leq i \leq T$, and note that $s_0 = s_*$ and $s_T = s^*$. Let also $m_i := P_N(s_i)$, for all $0 \leq i \leq T$, where $P_N : \mathbb{M} \to \mathbb{M}_N$ denotes the orthogonal projection. This construction is illustrated on Figure 5. The proof, short and elementary, proceeds by estimating the distance from $m_i$ to $s_i$ and to $m_{i+1}$, and then summing over the index $0 \leq i \leq T$. 

11
\[ s_0 = s^* \]
\[ s_i = s(i/T) \]
\[ m_i := \pi_{M_N}(s_i) \]

Figure 5: The classical estimate in Theorem 1.4 is based on projecting the measure preserving maps \((s_i)_{i=0}^{T-1} \in \mathbb{S}^{T+1}\) onto the finite dimensional space \(M_N\). This procedure is symmetrical to the projection of \((m_i)_{i=1}^{T-1} \in M_N^{T-1}\) onto \(S\) involved in the discrete energy optimization \((9)\), see Figure 2.

**Distance from \(m_i\) to the set of incompressible maps.** Denote by \(h_N := N^{-\frac{1}{2}}\) the discretization scale, and recall that each region of the partition \(P_N\) of \(X\) has area \(1/N\) and diameter \(\leq C_p h_N\). Let \(s_i^P\) denote the mean of \(s_i\) on the region \(P\) of the partition \(P_N\), for all \(0 \leq i \leq T\). Then

\[
\|s_i - m_i\|^2 = \sum_{P \in P_N} \int_P |s_i(x) - s_i^P|^2 dx \leq C_{sb}(C_p h_N)^2 \sum_{P \in P_N} \int_P |\nabla s_i(x)|^2 dx = C h_N^2 \|
abla s_i\|^2,
\]

where the Sobolev inequality constant \(C_{sb}\) only depends on the dimension, and \(C := C_{sb} C_p^2\).

**Distance from \(m_i\) to \(m_{i+1}\).** The map \(P_N\) is 1-Lipschitz, as it is the orthogonal projection onto the linear subspace \(M_N\). Hence for any \(0 \leq i < T\)

\[
\|m_i - m_{i+1}\|^2 \leq \|s_i - s_{i+1}\|^2 \leq \frac{1}{T} \int_{i/T}^{(i+1)/T} \|\dot{s}(t)\|^2 dt.
\]

**Summation and conclusion.** Summing \((17)\) and \((18)\) over \(0 \leq i \leq T\) we obtain

\[
\mathcal{E}(T, N, \lambda; m) \leq T \sum_{0 \leq i < T} \|m_{i+1} - m_i\|^2 + \lambda \sum_{0 \leq i \leq T} \|m_i - s_i\|^2
\leq \sum_{0 \leq i < T} \int_{i/T}^{(i+1)/T} \|\dot{s}(t)\|^2 dt + \lambda \sum_{0 \leq i \leq T} C h_N^2 \|
abla s_i\|^2
\leq d^2(s^*, s^*) + C' Th_N^2 \lambda,
\]

where \(C' = C \|s\|_{L^\infty([0,1], H^1(X))}\), which concludes the proof.

### 4 Relaxed estimate

We prove the relaxed estimate in Theorem 1.4 using a quantization of the generalized flow minimizing the relaxed geodesic distance \((3)\), in other words we approximate the solution \(\mu \in \text{Prob}(\Omega)\) with probability measures \((\mu_N)_{N \geq 1}\) equidistributed on a family of \(N\) paths. This quantization is a counterpart of the partition \(P_N\) of the domain \((X, \text{Leb})\) used for the classical estimate \((3)\) which amounts to quantize the initial positions of the fluid particles.
Figure 6: Left: Illustration of measure quantization. Two absolutely continuous probability measures over the disk (with constant density and a truncated Gaussian density) are approximated by finite collections of Dirac masses (shown as black dots) using the algorithm of De Goes et al [CGBOD12]. Right: Covering of the coast of England with $N$ balls of minimal radius, as in (19). Image by A. Monnerot-Dumaine, source Wikipedia.

The proof is split into four parts. In §4.1, we introduce the framework of measure quantization. In §4.2, we specialize it to the case of Brenier’s generalized flows. In §4.3, we perform a permutation of the obtained quantization, so as to match the boundary conditions. The announced energy estimate is finally proved in §4.4.

### 4.1 Box and quantization dimensions

In sampling theory, a natural objective is to approximate a given measure with a finite sum of Dirac masses in the Wasserstein distance, or to approximate a given set with a finite point set in the Hausdorff distance, see Figure 6. The quantization dimension of a measure, and the box dimension of a set, are defined as the optimal convergence rates of these approximation procedures.

We denote by $\delta_x$ the Dirac probability measure concentrated at a point $x$. The Hausdorff distance between two closed non-empty subsets $A, B$ of a metric space is defined by

$$\text{Hauss}(A, B) := \max \left\{ \sup_{a \in A} d_B(a), \sup_{b \in B} d_A(b) \right\}, \quad \text{where } d_Y(x) := \inf_{y \in Y} d(x, y).$$

**Definition 4.1.** Let $\mathbb{H}$ be a metric space, let $\mu$ be a probability measure on $\mathbb{H}$, and let $\Gamma \subseteq \mathbb{H}$ be closed and non-empty. For all $N \geq 1$ denote

$$h_N(\mu) := \inf_{\omega \in \mathbb{H}^N} W_2\left(\mu, \frac{1}{N} \sum_{1 \leq i \leq N} \delta_{\omega_i}\right), \quad r_N(\Gamma) := \inf_{\omega \in \mathbb{H}^N} \text{Hauss} \left(\Gamma, \{\omega_i\}_{i=1}^N\right).$$

The quantization dimension of $\mu$, and the (upper) box dimension of $\Gamma$, are defined by

$$D_{\text{quant}}(\mu) := \limsup_{N \to \infty} \frac{\ln N}{-\ln h_N(\mu)}, \quad D_{\text{box}}(\Gamma) := \limsup_{N \to \infty} \frac{\ln N}{-\ln r_N(\Gamma)}.$$ 

The box dimension $D_{\text{box}}$ of a set — also called the Minkowski dimension — is a variant of the Hausdorff dimension in which the set of interest if covered with balls of identical radius. Indeed, one easily shows that $r_N(\Gamma)$ is the minimal radius allowing to cover $\Gamma$ with $N$ balls

$$r_N(\Gamma) := \inf_{\omega \in \mathbb{H}^N} \min \left\{ r \geq 0; \Gamma \subseteq \bigcup_{1 \leq i \leq N} \overline{B}(\omega_i, r) \right\}. \quad (19)$$
Box and Hausdorff dimension coincide for compact manifolds, but differ in general. For instance, all countable sets have Hausdorff dimension zero, whereas one can check that

\[ D_{\text{box}}\left(([0,1] \cap \mathbb{Q})^d\right) = d, \quad D_{\text{box}}\left(\left\{ \frac{1}{n}; n \in \mathbb{N}^* \right\}\right) = \frac{1}{2}. \]

The quantization dimension of a measure is bounded above by the box dimension of its support, as shows the following elementary result of quantization theory. We refer the reader to [GG92] for more details on this rich subject.

**Proposition 4.2.** Let \( \mathbb{H} \) be a metric space, and let \( \mu \in \text{Prob}(\mathbb{H}) \) be supported on a set \( \Gamma \). Then \( D_{\text{quant}}(\mu) \leq \max\{2, D_{\text{box}}(\Gamma)\} \). More precisely for any \( D > 0 \), one has as \( N \to \infty \)

\[ r_N(\Gamma) = O(N^{-\frac{b}{2D}}) \quad \Rightarrow \quad h_N(\mu) = O \left\{ \begin{array}{ll}
N^{-\frac{b}{2D}} & \text{if } D > 2, \\
N^{-\frac{1}{2} \ln N} & \text{if } D = 2, \\
N^{-\frac{1}{2}} & \text{if } D < 2.
\end{array} \right. \]  

(20)

**Proof.** Let \( N \in \mathbb{N} \) be fixed. For each \( 1 \leq i \leq N \) let \( M_i \subseteq \mathbb{H} \) be a set of \( i \) points such that \( \Gamma \subseteq \cup_{i \in M_i} B(\omega_i, 2r_i) \), with \( r_i := r_i(\Gamma) \). We construct a sequence of points \( \omega_i \in \mathbb{H} \), and an increasing sequence of measures \( \rho_i \) supported on \( \Gamma \) and of mass \( i/N \), inductively starting with \( i = N \) and finishing with \( i = 1 \). Initialization: \( \rho_N := \mu \).

Induction: for each \( 1 \leq i \leq N \), we construct \( \omega_i \) and \( \rho_{i-1} \) in terms of \( \rho_i \). Let indeed \( \omega_i \in M_i \) be such that \( B_i := B(\omega_i, 2r_i) \) satisfies \( \rho_i(B_i) > 1/N \). Such a point exists since \( |\rho_i| = i/N \), \( \#(M_i) = i \), and \( \text{supp}(\rho_i) \subseteq \Gamma \). Then let \( \rho_{i-1} := \rho_i - \frac{1}{N\rho_i(B_i)} \rho_i \), so that \( \rho_i - \rho_{i-1} \) is a non-negative measure of mass \( \frac{1}{N} \) supported on \( B_i \). One has

\[ h_N(\mu)^2 \leq W_2^2 \left( \mu, \frac{1}{N} \sum_{1 \leq i \leq N} \delta_{\omega_i} \right) \leq \sum_{1 \leq i \leq N} W_2^2 \left( \rho_i - \rho_{i-1}, \frac{1}{N} \delta_{\omega_i} \right) \leq \frac{1}{N} \sum_{1 \leq i \leq N} (2r_i)^2. \]

The comparison \((20)\) of the decay rates of \( h_N(\mu) \) and \( r_N(\Gamma) \) immediately follows. Finally the comparison of the dimensions follows from \((20)\).

\[ \square \]

### 4.2 Quantization dimension of a generalized flow

We specialize in this subsection the measure \( \mu \), support \( \Gamma \) and embedding metric space \( \mathbb{H} \) to which we apply the results of §4.1. Let \( \mu \in \text{Prob}(\Omega) \) be a generalized flow minimizing the relaxed geodesic distance \((\ref{eq:relaxed_geodesic_distance})\). This measure is concentrated on the set \( \Gamma \) of paths obeying Newton’s second law of motion

\[ \Gamma := \{ \omega \in C^2([0,1], X); \forall t \in [0,1], \hat{\omega}(t) = -\nabla p(t, \omega(t)) \}, \]  

(21)

where the pressure gradient \( \nabla p : [0,1] \times X \to \mathbb{R}^d \) is assumed to have Lipschitz regularity, following the assumptions of Theorem \((\ref{thm:newton_second_law})\). We regard \( \Gamma \) as embedded in the Hilbert space \( \mathbb{H} := H^1([0,1], \mathbb{R}^d) \), which plays a natural role in the problem of interest \((\ref{eq:problem_of_interest})\) and is equipped with the norm

\[ \|\omega\|_{\mathbb{H}}^2 := \int_0^1 |\omega|^2 + |\hat{\omega}|^2. \]

Note that \( \mathbb{H} \) continuously embeds in \( C^0([0,1], \mathbb{R}^d) \), hence the evaluation maps \( e_t : \mathbb{H} \to \mathbb{R}^d : \omega \mapsto \omega(t) \) are continuous with a common Lipschitz constant denoted \( C_\epsilon \).
Notation 4.3 (Problem constants). The following quantities are referred to as the problem constants: the dimension $d$, the constant $C_P$ related to the partitions, the Lipschitz regularity constants $C_e$ and $C^*$ of the boundary conditions $s^{-1}_e$ and $s^*$, the maximum norm and the Lipschitz regularity constant of the pressure gradient $\nabla p$. Given two expressions $A, B$, we write $A \lesssim B$ iff $A \leq CB$ for some constant $C$ that only depends on the problem constants.

Using a general existence and stability result for ODEs, Lemma 4.4, we show that $\Gamma$ is in bijection with a compact subset of $\mathbb{R}^{2d}$, in Lemma 4.5.

Lemma 4.4. Let $F \in C^0([0, 1] \times \mathbb{R}^n, \mathbb{R}^n)$ be Lipschitz in the second variable, uniformly with respect to the first variable: $\exists L, \forall t \in [0, 1], \forall y_1, y_2 \in \mathbb{R}^n, |F(t, y_1) - F(t, y_2)| \leq L|y_1 - y_2|$. Then the map $\mathbb{R}^n \to L^2([0, 1], \mathbb{R}^n)$, associating to each $y_0 \in \mathbb{R}^n$ the solution to the ODE $y'(t) = F(t, y(t))$ with initial condition $y(0) = y_0$, is bi-Lipschitz onto its image with regularity constant $e^L$.

Proof. The Picard-Lindelöf/Cauchy-Lipschitz Theorem [CL55] guarantees the existence of a unique solution to the considered ODE. If $y_1, y_2$ are two such solutions, then for any $t \in [0, 1]$

$$|\dot{y}_1(t) - \dot{y}_2(t)| = |F(t, y_1(t)) - F(t, y_2(t))| \leq L|y_1(t) - y_2(t)|$$

Thus for any $t \in [0, 1]$

$$e^{-Lt}|y_1(0) - y_2(0)| \leq |y_1(t) - y_2(t)| \leq e^{Lt}|y_1(0) - y_2(0)|,$$

hence by integration over $t \in [0, 1]$, as announced

$$e^{-L}|y_1(0) - y_2(0)| \leq \|y_1 - y_2\|_{L^2([0, 1])} \leq e^L|y_1(0) - y_2(0)|.$$

The image of the generalized flow $\mu$ by the map of initial position and momentum, used in the next lemma, is often called a minimal measure [BFS09].

Lemma 4.5. The map $E_0 : \Gamma \to X \times \mathbb{R}^d : \omega \mapsto (\omega(0), \dot{\omega}(0))$ is bijective and bi-Lipschitz onto its image, which is a compact set. The Lipschitz regularity constants, and the image diameter, can be bounded in terms of the problem constants, see Notation 4.3.

Proof. The function $F(t, x, v) := (v, -\nabla p(t, x))$ is Lipschitz on $[0, 1] \times X \times \mathbb{R}^d$, with a regularity constant determined by that of $\nabla p$. It can be extended to $[0, 1] \times \mathbb{R}^{2d}$. Applying Lemma 4.4 to $F$ in dimension $n = 2d$, we obtain as announced that $E_0$ is bi-Lipschitz onto its image. Note that the norm $\|\omega, \dot{\omega}\|_{L^2([0, 1])}$ appearing in this estimate is precisely $\|\omega\|_{\mathcal{H}}$.

By construction, $\omega(t)$ and $\dot{\omega}(t)$ are uniformly bounded for all $\omega \in \Gamma$, and all $t \in [0]$, respectively by the diameter of $X$ and the maximum norm of $\nabla p$. This implies an upper bound on $\dot{\omega}(0)$, observing for instance that

$$|\omega(0) - \omega(1)| = \left| \int_0^1 \dot{\omega}(t) \, dt \right| \geq |\dot{\omega}(0)| - \int_0^1 |\dot{\omega}(t) - \dot{\omega}(0)| \, dt \geq |\omega(0)| - \int_0^1 |\dot{\omega}(t)| \, dt.$$

As announced, the image of $\Gamma$ by $E_0$ is bounded, hence compact since it is clearly closed.

Since there is no ambiguity, we denote in the rest of this section $h_N := h_N(\mu)$. The information gathered on the set $\Gamma$ supporting $\mu$ yields upper and lower bounds on the decay rate of $(h_N)$, obtained respectively in Corollary 4.6 and Proposition 4.7.

Corollary 4.6. One has $h_N \lesssim N^{-\frac{1}{2d}}$ (resp. $h_N \lesssim N^{-\frac{1}{2}} \sqrt{\ln N}$ if $d = 1$) for all $N \geq 2$. 

15
Proof. By Lemma 4.5, the set $\Gamma$ is in bi-Lipschitz bijective with a compact set $K \subseteq \mathbb{R}^d$. Hence $r_N(\Gamma) \lesssim r_N(K) \lesssim N^{-\frac{1}{2}}$, and the upper estimate follows from (20).

The quantization scale $h_N$ is also bounded below, and is minimal for classical solutions.

**Proposition 4.7.** One has $h_N \gtrsim N^{-\frac{1}{2}}$ for all $N \geq 1$. If the generalized flow $\mu$ in fact represents a classical solution $s$ to Euler’s equations, and $\nabla s$ is bounded on $[0,1] \times X$, then this lower estimate is sharp: $h_N \lesssim N^{-\frac{1}{2}}$.

**Proof.** Since $X$ is a domain of unit area, there exists $c > 0$ depending only on the dimension $d$ and such that $W_2(\text{Leb},\nu_N) \geq cN^{-\frac{1}{2}}$ for any measure $\nu_N$ supported at $N$ points of $\mathbb{R}^d$. The first point follows: for any measure $\mu_N$ supported at $N$ points of $\mathbb{H}$

$$cN^{-\frac{1}{2}} \leq W_2(\text{Leb}, \nu_0 \# \mu_N) = W_2(\nu_0 \# \mu, \nu_0 \# \mu_N) \leq C_\epsilon W_2(\mu, \mu_N) = C_\epsilon h_N.$$

Second point: for each $x \in X$, introduce the path $\omega_x : [0,1] \to \mathbb{R}^d : t \mapsto s(t,x)$. Then $\Phi : (X, \text{Leb}) \to (\Gamma, \mu) : x \mapsto \omega_x$ is measure preserving and Lipschitz, with regularity constant denoted $C_\Phi$ (which we regard as a problem constant). Let $\nu_N$ be a discrete probability measure, with one Dirac mass of weight $1/N$ in each region of the partition $\mathcal{P}_N$. Since these regions have diameter $\lesssim C_\mathcal{P} N^{-\frac{1}{4}}$, we conclude that

$$h_N \leq W_2(\mu, \Phi \# \nu_N) = W_2(\Phi \# \text{Leb}, \Phi \# \nu_N) \leq C_\Phi W_2(\text{Leb}, \nu_N) \leq C_\Phi C_\mathcal{P} N^{-\frac{1}{2}}. \quad \square$$

### 4.3 Permutation of the quantization of $\mu$ and boundary conditions

We have shown that the generalized flow, solution to Brenier’s relaxation of Euler’s equations, could be approximated (quantized) by a finite family of particle paths, with a controlled convergence rate. This is not yet sufficient however to construct a good candidate for the discrete energy (9), despite its relaxed reformulation (24). For that purpose one needs to permute the paths, so as to match the boundary conditions, as required by the energy term (16).

We show in Lemma 4.8 that an optimal quantization exists, we suitably permute it in Lemma 4.9, and estimate a first boundary term, and we estimate the second boundary term in Proposition 4.10. In this subsection and the next, we fix the integer $N$ and allow ourselves a slight abuse of notation: elements $\omega_j, P_j, \rho_j, \ldots$ indexed by $1 \leq j \leq N$ do implicitly depend on $N$, although that second index $\omega_j^N, P_j^N, \rho_j^N, \ldots$ is omitted for readability.

**Lemma 4.8.** The infimum defining $h_N$ is attained, see Definition 4.1. As a result there exists $(\omega_j)_{j=1}^N \in \mathbb{H}^N$ and probability measures $(\rho_j)_{j=1}^N$ on $\Gamma$ such that

$$\mu = \frac{1}{N} \sum_{1 \leq j \leq N} \rho_j \quad h_N^2 = \frac{1}{N} \sum_{1 \leq j \leq N} \int_\Gamma \|\omega - \omega_j\|^2 d\rho_j(\omega) = (22)$$

Furthermore, $\omega_j$ is the barycenter of $\rho_j$ for each $1 \leq j \leq N$.

**Proof.** Let $(\omega_j)_{j=1}^N$ be a candidate quantization, and let $\pi$ be the transport plan associated to

$$W_2^2(\frac{1}{N} \sum_{j=1}^N \delta_{\omega_j}, \mu).$$

Then the measures $\rho_j : A \mapsto N \pi(\{\omega_j\} \times A), 1 \leq j \leq N$, are probabilities which average to $\mu$, and the transport cost is the RHS of (22). The quantization energy, i.e. the squared Wasserstein distance, is decreased when replacing $\omega_j$ with the barycenter $b_j$ of $\rho_j, 1 \leq j \leq N$, by the amount $\frac{1}{N} \sum_{j=1}^N |\omega_j - b_j|^2$. Hence $\omega_j = b_j$ for all $1 \leq j \leq N$ if the quantization is optimal. Note also that the barycenter of $\rho_j$ belongs to $G := \text{Hull}(\Gamma)$ by construction.
Since $\Gamma$ is a compact subset of a Hilbert space, the convex hull closure $G$ is also compact, for the strong topology induced by $\| \cdot \|_H$. The quantization energy $(\omega_j)_{j=1}^N \mapsto W_2^2(\frac{1}{N} \sum_{j=1}^N \delta_{\omega_j}, \mu)$ attains its minimum on $G^N$ by compactness, and by the previous argument it is the global minimum on $H^N$. \hfill \Box

Let $\mu_N$ denote the equidistributed probability on the set $\{\omega_j; 1 \leq j \leq N\}$ of Lemma 4.8.

**Lemma 4.9.** The paths $(\omega_j)_{j=1}^N$ of the quantization $\mu_N$, and the regions $(P_j)_{j=1}^N$ of the partition $\mathcal{P}_N$, can be indexed in such way that

$$\sum_{1 \leq j \leq N} \int_{P_j} |\omega_j(0) - s_*(x)|^2 dx \lesssim h_N^2. \quad (23)$$

**Proof.** Let $(P_j)_{j=1}^N$ be an arbitrary indexation of $\mathcal{P}_N$. Let $a_j$ be the barycenter of region $P_j$, and $b_j$ the barycenter of the image region $s_*(b_j)$. For any $1 \leq j \leq N$ one has by assumption

$$\int_{P_j} |b_j - s_*(x)|^2 dx \leq \int_{P_j} |s_*(a_j) - s_*(x)|^2 dx \leq C_*^2 \int_{P_j} |a_j - x|^2 dx \leq \frac{1}{N}(C_* C_{\mathcal{P}} N^{-\frac{1}{2}})^2,$$

where $C_*$ denotes the Lipschitz regularity constant of $s_*^{-1}$. Denoting by $\nu_N$ the discrete measure equidistributed at the $N$ points $(b_j)_{j=1}^N$, we obtain

$$W_2(\nu_N, \text{Leb}) \leq \sqrt{\sum_{1 \leq j \leq N} \int_{P_j} |b_j - s_*(x)|^2 dx} \lesssim N^{-\frac{1}{2}}.$$

On the other hand $W_2(\text{Leb}, e_0 \# \mu_N) \leq C_e W_2(\mu, \mu_N) = C_e h_N$. Thus $W_2(\nu_N, e_0 \# \mu_N) \lesssim h_N$, since $W_2$ defines a distance, and since $h_N \gtrsim N^{-\frac{1}{2}}$ by Proposition 4.7. This optimal transport problem between the discrete measures $\nu_N$ and $e_0 \# \mu_N$ determines an optimal assignment $\Gamma_N \to B_N$. Up to a permutation of the paths $(\omega_j)_{j=1}^N$, we assume that this assignment is represented by the common indexation $(\omega_j)_{j=1}^N$ of $\Gamma_N$ and $(b_j)_{j=1}^N$ of $B_N$. Finally

$$\sum_{1 \leq j \leq N} \int_{P_j} |\omega_j(0) - s_*(x)|^2 dx = \sum_{1 \leq j \leq N} \int_{P_j} |b_j - s_*(x)|^2 dx + W_2^2(\nu_N, e_0 \# \mu_N) \lesssim h_N^2. \quad \Box$$

**Proposition 4.10.** Using the indexation of Lemma 4.9 one has

$$\sum_{1 \leq j \leq N} \int_{P_j} |\omega_j(1) - s^*(x)|^2 dx \leq C h_N^2.$$

**Proof.** The generalized boundary condition of (3) states that $\omega(1) = s^*_*(\omega(0))$ for $\mu$-almost every $\omega \in \Gamma$, where $s^*_* := s^* \circ s_*^{-1}$. Denoting by $C_*^s$ the Lipschitz regularity constant of $s_*^s$, we obtain for any $1 \leq j \leq N$ and any $x \in X$

$$|\omega_j(1) - s^*(x)|^2 = \left| \int_{[\omega]} s_*(\omega_0) - s_*(x) \, dp_j(\omega) \right|^2 \leq \int_{[\omega]} |s_*(\omega_0) - s_*(x)|^2 \, dp_j(\omega) \leq (C_*^s)^2 \int_{[\omega]} |\omega(0) - s_*(x)|^2 \, dp_j(\omega) \leq 2(C_*^s)^2 \left( \int_{[\omega]} \omega(0) - \omega(0)^2 \, dp_j(\omega) + |\omega_j(0) - s_*(x)|^2 \right).$$

By summation and integration we conclude, using Lemma 4.9 in the second line,

$$\sum_{1 \leq j \leq N} \int_{P_j} |\omega_j(1) - s^*(x)|^2 dx \lesssim \sum_{1 \leq j \leq N} \frac{1}{N} \int_{[\omega]} |\omega_j(1) - \omega(0)|^2 \, dp_j(\omega) + \sum_{1 \leq j \leq N} \int_{P_j} |\omega_j(0) - s_*(x)|^2 dx \leq C_*^s W_2^2(\mu_N, \mu) + C h_N^2 \lesssim h_N^2. \quad \Box$$
4.4 Final estimate

We conclude in this subsection the proof of Theorem 1.4 (Relaxed estimate). Let \( \mu \in \text{Prob}(\Omega) \) be a generalized flow minimizing \([3]\), with an associated Lipschitz pressure gradient. We fix the parameters \((T, N)\), and consider an optimal quantization \( \mu_N \) supported on \( N \) paths \( (\omega_j)_{j=1}^N \) as in Lemma 4.8. For each \( 0 \leq i \leq T \), let \( m_i \in \mathbb{N} \) be the piecewise constant map on the partition \( \mathcal{P}_N \) defined by

\[
\forall 1 \leq j \leq N, \forall x \in P_j, \ m_i(x) := \omega_j(i/T).
\]

In the following, we bound each of the terms of the energy \( E(T, N, \lambda; m) \geq E(T, N, \lambda) \). By Lemma 4.9 and Proposition 1.2, one has respectively

\[
\|m_0 - s_*\|^2 \lesssim h_N^2, \quad \|m_T - s^*\|^2 \lesssim h_N^2.
\]

Regarding the distance to incompressible maps, one has for any \( 1 \leq i < T \), with \( t := i/T \)

\[
\inf_{s \in S} \|m_i - s\| = W_2(\text{Leb}, e_\lambda \# \mu_N) = W_2(e_\lambda \# \mu, e_\lambda \# \mu_N) \leq C e W_2(\mu, \mu_N) = C e h_N.
\]

We use the Cauchy-Schwartz inequality to bound the action:

\[
T \sum_{0 \leq i < T} \|m_{i+1} - m_i\|^2 = \frac{1}{N} \sum_{1 \leq j \leq N} T \sum_{0 \leq i < T} \left| \omega_j \left( \frac{i+1}{T} \right) - \omega_j \left( \frac{i}{T} \right) \right|^2 \leq \frac{1}{N} \sum_{1 \leq j \leq N} \int_0^1 |\dot{\omega}_j(t)|^2 dt
\]

\[
= \frac{1}{N} \sum_{1 \leq j \leq N} \int_0^1 \int_\Gamma \dot{\omega}_j(\omega) \, d\rho_j(\omega) \leq \frac{1}{N} \sum_{1 \leq j \leq N} \int_0^1 \int_\Gamma |\dot{\omega}_j|^2 d\rho_j(\omega) dt = d_2^2(s_*, s^*).
\]

Concluding, the value \( E(T, N, \lambda) \) is bounded by

\[
T \sum_{0 \leq i < T} \|m_{i+1} - m_i\|^2 + \lambda \left( \|m_0 - s_*\|^2 + \|m_T - s^*\|^2 + \sum_{1 \leq i < T} \inf_{s \in S} \|m_i - s\|^2 \right) \leq d_2^2(s_*, s^*) + O(T h_N^2 \lambda).
\]

5 Numerical experiments

5.1 Minimization algorithm and choice of penalization

We rely on a quasi-Newton method to compute a (local) minimum of the discretized problem \([3]\), as summarized in Algorithm 1. This means that we need to compute the value of the functional

\[
m \in \mathbb{M}_N^{T+1} \mapsto T \sum_{0 \leq i < T} \|m_{i+1} - m_i\|^2 + \lambda \left( \|m_0 - s_*\|^2 + \|m_T - s^*\|^2 + \sum_{1 \leq i < T} d_2^2(m_i) \right).
\]

and its gradient, where \( d_2^2(m) = \inf_{s \in S} \|m - s\|^2 \). The only difficulty is to evaluate the squared distance \( d_2^2 \) to the set of measure-preserving vector fields and its gradient. As explained in the introduction, Brenier’s Polar Factorization Theorem implies that for any vector-valued function \( m \in \mathbb{M}, \)

\[
d_2^2(m) = W_2^2(m \# \text{Leb}, \text{Leb}).
\]

When \( m \) belongs to \( \mathbb{M}_N \), the measure \( m \# \text{Leb} \) is finitely supported, and the computation of the Wasserstein distance can be performed using a solver for semi-discrete optimal transport, such as \([\text{AHA98}, \text{Mer11}, \text{IGBOD12}, \text{Lév14}]\). The next proposition gives an explicit formulation for the gradient in term of the optimal transport plan. Note that the expression of the gradient of
the semi-discrete Kantorovich functional with respect to the position of the points also appears in the appendix of [1GB0D12].

Recall that \( M_N \) is the set of piecewise constant functions on the tessellation \( P_N := (P_j)_{1 \leq j \leq N} \) of \( X \). The diagonal \( D_N \) in \( M_N \) is the set of functions \( m \) in \( M_N \) such that \( m(P_j) = m(P_k) \) for some \( j \neq k \). The set \( M_N \setminus D_N \) is a dense open set in \( M_N \).

**Proposition 5.1.** The functional \( d^2_\# \) is differentiable almost everywhere on \( M_N \) and continuously differentiable on \( M_N \setminus D_N \). The gradient of \( d^2_\# \) at \( m \in M_N \setminus D_N \) is explicit: with \( x_j = m(P_j) \),

\[
\nabla d^2_\#(m)\big|_{P_j} = 2(x_j - \text{bary}(T^{-1}(x_j)))
\]

where \( T : X \rightarrow m(X) \) is the piecewise constant optimal transport map between \( \text{Leb} \) and the finitely supported measure \( m \# \text{Leb} \), and \( \text{bary}(S) = \int_S x \, dx / \text{Leb}(S) \) is the isobaricenter of \( S \).

**Proof.** The functional \( F := d^2_\# - \| \cdot \|^2 \) is concave as an infimum of linear functions:

\[
F(m) = d^2_\#(m) - \|m\|^2 = \inf_{s \in S} \|m - s\|^2 - \|m\|^2 = \inf_{s \in S} \left[ -2\langle m | s \rangle + \|s\|^2 \right],
\]

where \( \langle \cdot, \cdot \rangle \) denotes the \( L^2(X) \) scalar product. This implies in particular that \( F \) and therefore \( d^2_\# \) is differentiable almost everywhere on \( M_N \). Given \( m \in M_N \setminus D_N \), define \( x_j = m(P_j) \) and let \( T : X \rightarrow \mathbb{R}^d \) be the optimal transport plan from \( \text{Leb} \) to \( m \# \text{Leb} = \frac{1}{N} \sum_{j=1}^{N} \delta_{x_j} \). The transport plan is indeed always representable by a function when the source measure is absolutely continuous with respect to the Lebesgue measure. Let \( V_j = T^{-1}(x_j) \) be the partition of \( X \) induced by this transport plan. Then

\[
F(m) = W^2_2(m \# \text{Leb}, \text{Leb}) - \|m\|^2 = \sum_{j=1}^{N} \int_{V_j} \|x_j - x\|^2 - \|x_j\|^2 \, dx
\]

\[
= \langle m | G(m) \rangle + \sum_{j=1}^{N} \int_{V_j} \|x\|^2 \, dx
\]

where \( G(m) \in M_N \) is the piecewise constant function on \( X \) given by \( G(m)|_{P_j} = -2 \text{bary}(V_j) \). For any \( m' \in M_N \) and \( x'_j = m'(V_j) \), one has

\[
F(m') = W^2_2(m' \# \text{Leb}, \text{Leb}) - \|m'\|^2 \leq \sum_{j=1}^{N} \int_{V_j} \|x'_j - x\|^2 - \|x'_j\|^2 \, dx
\]

\[
= F(m) + \langle m' - m | G(m) \rangle
\]

This shows that \( G(m) \) belongs to the superdifferential to \( F \) at \( m \). In addition, by the continuity of optimal transport plans, the map \( m \in M_N \setminus D_N \mapsto G(m) \) is continuous. To summarize, on the open domain \( M_N \setminus D_N \) the concave function \( F \) possesses a continuous selection of supergradient. This implies that \( F \) is of class \( C^1 \) on this domain, with \( \nabla F(m) = G \), and the result follows. \( \square \)

**Remark 5.2 (Computation of \( d^2_\# \)).** The computation of the squared distance to measure-preserving maps \( d^2_\# \) and its gradient rely on the variational approach used in the proof of the above proposition. We use the CGAL library \([CGAL]\) to evaluate \( F \) and its first and second derivatives, and a simple damped Newton’s algorithm to compute its maximum. The implementation is available at \url{https://github.com/mrgt/PyMongeAmpere}. 

19
Construction of the initial solution  Since the discrete energy (8) is non-convex, the construction of the initial guess is important. We follow a time-refinement strategy already used by Brenier \[Bre08\] to construct a good initial guess. Assuming that we have already a local minimizer for $T_k = 2^k + 1$, we use linear interpolation to construct an initial guess for $T_{k+1} = 2^{k+1} + 1$. The optimization is then performed from this initial guess, using a quasi-Newton algorithm for the energy (8).

Choice of the penalization parameter  The optimal choice of $\lambda$ in (8) depends on the quantization dimension $D = D_{\text{quant}}(\mu)$ of the generalized solution $\mu \in \text{Prob}(\Omega)$ that one expects to recover: namely $\lambda_N = N^{-\frac{1}{D}}$, see Remark 1.5. We call $D$ the flow dimension, and regard it as the intrinsic dimensionality of the problem which determines its computational difficulty. For a classical solution, this dimension agrees with the ambient dimension i.e. $D = d$, while for a non-deterministic solution the quantization dimension can be up to $2d$. Intermediate dimensions $d < D < 2d$ are also common [Bre89]. In our numerical experiments we set $\lambda_N = N^{\frac{1}{D}}$, a decision justified a-posteriori by the numerical estimation of the quantization dimension of the computed solution, see Figure 8.

Note that the numerical error in (1.5) is governed (for a fixed number $T$ of time steps) by the quantity $\lambda^{-1} + h_N^2 \lambda$, and that $h_N = O(N^{-\frac{1}{D}})$ under the assumptions of Theorem 1.4. The choice $\lambda_N = N^{\frac{1}{D}}$ thus yields a convergent scheme whenever $\alpha > d$, although convergence rates are improved if $\alpha$ is close to the flow dimension $D$, so that $\lambda_N \approx N^{\frac{1}{D}} \approx h_N^{-1}$.

Algorithm 1  Computation of a (local) minimizer for (24).

For $k = 1 \ldots k_{\max}$

\begin{align*}
T &:= 2^k \\
& \text{for all even } t \in \{0, \ldots, T\}, \text{let } m_i^k := m_{i/2}^{k-1} \quad \text{initialize discrete geodesic} \\
& \text{for all odd } t \in \{1, \ldots, T\}, \text{let } m_i^k := \frac{1}{2}(m_{i-1}^k + m_{i+1}^k) \quad \text{optimize} \\
\text{Until convergence do} \\
& \text{for all } i, \text{compute } d_S(m_i) \text{ and } \nabla d_S(m_i) \quad \text{see Rem. 5.2} \\
& \text{compute the discrete path energy and its gradient} \quad \text{see Eq. (24)} \\
& \text{update } (m_i^k)_{0 \leq i \leq T} \text{using the L-BFGS scheme} \quad \text{[BLNZ95]} \\
\end{align*}

5.2 Visualization of generalized solution

The main interest of numerical experimentation is to visualize generalized solutions to Euler’s equation, or equivalently generalized geodesics between two measure-preserving diffeomorphisms $s \ast, s^\ast$ in $S$.

5.2.1 Gradient of the pressure

Consider a minimizer of the discretized energy (8). Given $i \in \{1, \ldots, T-1\}$, $m_i$ minimizes over $M_N$ the functional $m \mapsto T((m - m_{i-1})^2 + (m_{i+1} - m)^2) + \lambda d_S^2(m)$. This gives

$$T^2(m_{i-1} - 2m_i + m_{i+1}) = T\lambda \nabla d_S^2(m_i).$$

(26)

This equation is a discretized counterpart of the rule that the acceleration of a geodesic on an embedded manifold, is normal to that manifold (here $S$ plays the role of the manifold, embedded in $M$, which is internally approximated by the linear space $M_N$). The second order difference
$T^2(m_{i-1} - 2m_i + m_{i+1})$ approximates a second derivative in time. Comparing (26) to (6), we see that the right hand-side of (26) can be used as an estimation of (minus) the gradient of the pressure.

5.2.2 Geometric data analysis

As in the proof of Theorem 1.4, the discrete minimizer of (8) can be converted to a collection of $N$ piecewise-linear curves $\{\omega_1, \ldots, \omega_N\} = \Gamma_N$. We recall that the domain $X$ is partitioned into $N$ subdomains $(P_j)_{1 \leq j \leq N}$ with equal area and we let $\omega_j(i/T) \in \mathbb{R}^d$ be the point corresponding to the restriction of $m_i$ to the subdomain $P_j$, for each $0 \leq i \leq T$. Figure 3 illustrates this construction. We regard $\Gamma_N$ as embedded in the Hilbert space $\mathbb{H} := H^1([0,1], \mathbb{R}^2)$ which plays a natural role in the problem of interest, as in §4, and apply techniques from the field of geometric data analysis.

Clustering In order to better visualize the solution, we use the $k$-means algorithm to divide the set $\Gamma_N$ into $k$. A distinct particle color is attached to each cluster, see for instance Figure 10. The $k$-means algorithm consists in finding a local minimizer of the optimal quantization problem

$$
\min_{\ell_1, \ldots, \ell_k \in \mathbb{H}} \frac{1}{N} \sum_{\omega \in \Gamma_N} \min_{1 \leq i \leq k} \| \omega - \ell_i \|^2_H
$$

using a simple fixed point algorithm, and to divide $\Gamma_N$ into clusters $(C_i)_{1 \leq i \leq k}$ with

$$
C_i = \left\{ \omega \in \Gamma_N; \| \omega - \ell_i \|^2_H = \arg \min_{1 \leq j \leq k} \| \omega - \ell_i \|^2_H \right\}.
$$

Note that $l_1, \ldots, l_k$ automatically belong to $\text{Span}(\Gamma_N)$, hence to the $d(T + 1)$-dimensional linear subspace of $\mathbb{H}$ consisting of piecewise linear paths with nodes $\omega(t) \in \mathbb{R}^d$ at times $t = i/T$, $0 \leq i \leq T$. This makes (27) tractable.

Let $\mu$ be the probability measure supported on the set $\Gamma_N \subseteq \mathbb{H}$, with weight $1/N$ for each element. The $k$-means problem amounts to finding the probability measure $\mu_k$, supported on at most $k$ points of $\mathbb{H}$, which is the closest to $\mu$ w.r.t. the Wasserstein distance: (27) equals

$$
\min_{\#(\text{supp } \mu_k) \leq k} W^2_2(\mu, \mu_k).
$$

This quantization problem is closely related to the one defining $h_N(\mu)$ in Definition 4.1, up to the difference that the candidate measure $\mu_k$ need not be equidistributed on the $k$ points of its support.

Box dimension A natural objective is to estimate the quantization dimension $D_{\text{quant}}(\mu)$ of the generalized flow $\mu \in \text{Prob}(\Omega)$ minimizing the relaxed problem (3). The probability measure $\mu_N$ equidistributed on the set $\Gamma_N$ approximates $\mu$, hence we can expect the set $\Gamma_N$ to also approximate $\text{supp}(\mu)$. The quantization dimension $D_{\text{quant}}(\mu)$ is difficult to estimate, but by Proposition 4.2 it admits the simpler upper bound $D_{\text{box}}(\text{supp}(\mu))$. We estimate the latter by applying the furthest point sampling algorithm to the finite metric space $\Gamma_N$, which defines an ordering on the elements of $\Gamma_N$ as follows: let $\gamma_1$ be an arbitrary point of $\Gamma_N$ and define by induction

$$
\gamma_{i+1} := \arg \max_{\gamma \in \Gamma_N} d(\gamma, \{\gamma_1, \ldots, \gamma_i\})
$$

(28)
As in Definition 4.1 denote by \( r_i = r_i(\Gamma_N) \) is the smallest \( r \geq 0 \) such that \( \Gamma_N \) can be covered by \( i \) balls of radius \( r \). For \( 1 \leq i \leq N \), the ratio \( \log(i)/\log(1/r(\Gamma_N)) \) is expected to approximate \( \log(i)/\log(1/r_i(\text{supp}(\mu))) \) and thus the desired \( D_{\text{box}}(\text{supp} \mu) \).

Lemma 5.3. Let \( \gamma_i := \max_{\gamma \in \Gamma} d(\gamma, \{\gamma_1, \ldots, \gamma_i\}) \), where \( \gamma_i \) is defined as in (28). Then,

\[
\left( 1 - \frac{\log(2)}{\log(1/\varepsilon_i)} \right) \frac{\log(i)}{\log(1/\varepsilon_i)} \leq \frac{\log(i)}{\log(1/r_i)} \leq \frac{\log(i)}{\log(1/\varepsilon_i)}
\]

Proof. By construction, \( r_i \leq \varepsilon_i \). Moreover, the balls centered at the points \( \gamma_1, \ldots, \gamma_i \) and with radius \( \varepsilon_i/2 \) are disjoint, so that \( r_i \geq \varepsilon_i/2 \).

5.3 Test cases and numerical results

Our two test cases are constructed from two stationary solutions to Euler’s equation in 2D. Let \( s : \mathbb{R}_+ \to \mathbb{S} \) be a classical solution to Euler equation in Lagrangian coordinates [O], starting from the identity map. We solve the discretized version of the minimization problem (2)-(3), with \( s_* = s(0) = \text{Id} \) and \( s^* := s(t_{\text{max}}) \), where \( t_{\text{max}} > 0 \). For small values of \( t_{\text{max}} \) the solution to this boundary problem is simply the original classical flow \( s \), but for larger values a completely different generalized flow is obtained. In this case the geodesic \( s \) in the space of the measure preserving diffeomorphisms is no longer the unique shortest path between its boundary values \( s_* \) and \( s^* \). The first classical behavior is guaranteed if the pressure hessian satisfies

\[
\nabla^2 p \prec (\pi/t_{\text{max}})^2 \text{Id}
\]

uniformly on \([0, t_{\text{max}}] \times X\), see [O] and [Bre89]. In all the numerical experiments, the number of points is set to \( N = 10000 \) and the number of timesteps is \( T = 2^4 + 1 = 17 \).

5.3.1 Rotation of the disk

On the unit disk \( D = \{(x_1, x_2) \in \mathbb{R}^2; x_1^2 + x_2^2 \leq 1\} \), the simplest stationary solution to Euler’s equation (11) is given by a time-independent pressure field and speed:

\[
p(x_1, x_2) = \frac{1}{2}(x_1^2 + x_2^2), \quad v(x_1, x_2) = (-x_2, x_1).
\]

The corresponding Lagrangian flow \( s(t) \) is simply the rotation of angle \( t \). The largest eigenvalue of \( \nabla^2 p \) is 1 at every point in \( D \). Hence by (29) the flow of rotations is the unique minimizer to both the variational formulation (2) and its relaxation (3) with boundary values \( s_* = s(0) = \text{Id} \) and \( s^* = s(t_{\text{max}}) \), when \( t_{\text{max}} < \pi \). Uniqueness is lost at the critical time \( t_{\text{max}} = \pi \) which corresponds to a rotation of angle \( \pi \), so that the final diffeomorphism becomes \( s_* = s(\pi) = -\text{Id} \). In this situation, the minimization problem (2) has two classical solutions, namely the clockwise and counterclockwise rotations. The relaxation (3) has uncountably many generalized solutions such as, by linearity, superpositions of these two rotations.

Another explicit example of generalized solution was discovered by Brenier [Bre89]: given a point \( x \in D \) and a speed \( v \), denote by \( \omega_{x,v} \) the curve \( \omega_{x,v}(t) = x \cos(t) + v \sin(t), t \in [0, 1] \). Then, Brenier’s solution is obtained as the pushforward by the map \( (x, v) \mapsto \omega_{x,v} \in \Omega \) of the measure on \( D \times \mathbb{R}^2 \) defined by

\[
\mu(dx, dv) = \frac{1}{\pi} \mathcal{H}^2(dx) \otimes \frac{1}{2\pi \sqrt{1 - |x|^2}} \mathcal{H}^1|_{\{|v| = \sqrt{1 - |x|^2}\}}(dv),
\]

22
where $\mathcal{H}^k$ denotes the $k$-dimensional Hausdorff measure. In particular, the quantization dimension of the solution is $3 = 2 + 1$. We refer to [BFS09] for more examples of optimal flows, and construct four dimensional one. Let $\mu_r$ be defined by combining (i) a classical rotation on the annulus $D \setminus D(r)$, with $D(r) = \{ x \in \mathbb{R}^2; |x| \leq r \}$ and (ii) Brenier’s solution rescaled by a factor $r$ on the disc $D(r)$. Then $\mu_r$ is an optimal generalized flow of quantization dimension 3, whereas the averaged flow $\int_0^1 \mu_r dr$ is also optimal by linearity, and has quantization dimension 4.

**Numerical results** The numerical solutions computed by our algorithm for the critical time $t_{\text{max}} = \pi$ are highly non-deterministic. To see this, we select a small neighborhood around several points in the unit disk $D$ and look at the trajectories emanating from this small neighborhood. As shown in Figure 7, the trajectories emanating from each neighborhood at initial time tend to fill up the disk at intermediate times before gathering again on a small neighborhood at final time. In addition, each individual trajectory looks like an ellipse, as in Brenier’s explicit solution. Second, we estimate the box dimension of the support of the numerical solution (as explained in §5.2). The estimated dimension is slightly above 3.

### 5.3.2 Beltrami flow on the square

On the unit square $S = [-1/2, 1/2]^2$, we consider the Beltrami flow constructed from the time-independent pressure and speed:

$p(x_1, x_2) = \frac{1}{2} (\sin(\pi x_1)^2 + \sin(\pi x_2)^2)$

$v(x_1, x_2) = (-\cos(\pi x_1) \sin(\pi x_2), \sin(\pi x_1) \cos(\pi x_2))$

The maximum eigenvalue of the pressure Hessian $\nabla^2 p$ is $\pi^2$, and [Bre89] implies that the associated flow is minimizing $s_{\text{max}} = 0$ are highly non-deterministic. To see this, we select a small neighborhood around several points in the unit disk $D$ and look at the trajectories emanating from this small neighborhood. As shown in Figure 7, the trajectories emanating from each neighborhood at initial time tend to fill up the disk at intermediate times before gathering again on a small neighborhood at final time. In addition, each individual trajectory looks like an ellipse, as in Brenier’s explicit solution. Second, we estimate the box dimension of the support of the numerical solution (as explained in §5.2). The estimated dimension is slightly above 3.

**Numerical results** Our numerical results suggest the following observations. First, as shown in Figure 9, the computed solutions with boundary values $s_\star = \text{Id}$ and $s^\star = s(t_{\text{max}})$ approximate the classical flow if $t_{\text{max}} < 1$, and are non-deterministic generalized flows if $t_{\text{max}} > 1$. This suggests the sharpness of the bound given by [Bre89]. Interestingly, even for $t_{\text{max}} > 1$, the numerical solutions seem to remain deterministic in a neighborhood of the boundary of the cube. This can be seen more clearly in Figure 10, where the particles have been divided into clusters using the $k$-means algorithm (the clustering algorithm is explained in §5.2.2).

The pressure gradient is estimated as in §5.2.1 and is displayed in Figure 11. These pictures seem to indicate a loss of regularity of the pressure near the initial and final times. This corroborates the result of [AF07] according to which the pressure belongs to $L^2_{\text{loc}}(]0, T[, \text{BV}(X))$.

Figure 7 suggests that the even for $t_{\text{max}} = 1.5$, the reconstructed solution for the Beltrami flow are more deterministic than the solution to the disk inversion. We estimate the box dimension of the support of the solution using the method explained in §5.2.2. The results are displayed in Figure 5. The estimated dimension is $D = 2$ for the deterministic solution ($t_{\text{max}} = 0.9$) but it increases as the maximum time (and therefore the amount of non-determinism) increases. Finally, we note that the estimated dimensions for $t_{\text{max}} \in \{1.1, 1.3, 1.5\}$ seem to be strictly between 2 and 3, suggesting a fractal structure for the support of the solution. This would need to be confirmed by a mathematical study.
Software. The software developed for generating the results presented in this article is publicly available at [https://github.com/mrgt/EulerSemidiscrete](https://github.com/mrgt/EulerSemidiscrete)

Acknowledgement The authors thank Y. Brenier for constructive discussions and introducing them to the topic of Euler equations of inviscid incompressible fluids.

Figure 7: We select particles whose initial position lie in a small disk, and display their trajectories according to the computed solution to (8). (Top) For the inversion of the unit disk (Bottom) For the Beltrami flow on the square, with $t_{\text{max}} = 1.5$.

Figure 9: *(First row)* Beltrami flow in the unit square at various timesteps, a classical solution to Euler’s equation. The color of the particles depend on their initial position. *(Second to fifth row)* Generalized fluid flows that are reconstructed by our algorithm, using boundary conditions displayed in the first and last column. When $t_{\text{max}} < 1$ we recover the classical flow, while for $t_{\text{max}} \geq 1$ the solution is not classical any more and includes some mixing.

Figure 10: Using the $k$-means cluster algorithm, we cluster the reconstructed trajectories for the Beltrami flow in the square with $t_{\text{max}} = 1.5$ into 10 groups, whose particles are displayed with different colors. The resulting pictures suggest that close to the boundary of the square the movement of particle is clockwise and deterministic while in the interior the movement is highly non-deterministic and counter-clockwise.
