Abstract
An English entity linking (EL) workflow is presented, which combines the annotations of five public open source EL services. The annotations are combined through a weighted voting scheme inspired by the ROVER method, which had not been previously tested on EL outputs. The combined results improved over each individual system’s results, as evaluated on four different golden sets.

1 Introduction
The Entity Linking (EL) literature has shown that the quality of EL systems’ results varies widely depending on characteristic of the corpora they are applied to, or on the types of entities we need to link (Cornolti et al., 2013, Usbeck et al., 2015). For instance, a system that links to a wide set of entity types can be less accurate at basic types like Person, Location, Organization than systems specializing in those basic types.

A way to make up for the uneven performance of entity linking methods across corpora would be mixing different annotators’ results, so that the annotators’ strengths complement each other. This paper presents a method to combine the outputs of five open source entity linking systems, in order to obtain improved results. The method involves a weighted voting scheme that had not been previously applied to EL, and improves annotation results across four test-corpora.

The structure of the paper is as follows: Section 2 presents related work. Section 3 describes the combined entity linking system. Section 4 provides an evaluation of the system’s results and a discussion.

2 Related Work
General surveys on EL can be found in (Cornolti et al., 2013) and (Rao et al., 2013). Besides the EL literature, work on combining NLP annotators is particularly relevant for the present article.

The goal of combining different NLP systems is obtaining combined results that are better than the results of each individual system. Fiscus (1997) created the ROVER method, with weighted voting to improve speech recognition outputs. ROVER was found to improve parsing results by De la Clergerie et al. (2008). In Named Entity Recognition (NER), Rizzo et al. (2014) improved results combining systems via different machine learning algorithms.

In entity linking, the potential benefits of combining annotations have been explored before. Rizzo and Troncy (2012) describe the NERD system, which combines entity linkers. However, we are not aware of a system that, like ours, makes an automatic choice among the systems’ conflicting annotations, based on an estimate of each annotation’s quality. Our approach to choose among conflicting annotations is inspired by the ROVER method, which had not been previously attempted for EL to our knowledge. A further difference in our system is that the set of linkers we combine is public and open-source.
3 Combining Annotators

Our workflow performs English EL to Wikipedia, combining the outputs of the following EL systems: Tagme 1 (Ferragina and Scaiella, 2010), DBpedia Spotlight2 (Mendes et al. 2011), Wikipedia Miner3 (Milne and Witten, 2008a), AIDA4 (Hoffart et al., 2011) and Babelfy5 (Moro et al. 2014). A description of the different systems can be found in (Usbeck et al., 2015). The systems rely on a variety on algorithms and it can be expected that their results will complement each other.

3.1 Obtaining Individual Annotator Outputs

First of all, a client requests the annotations for a text from each linker’s web-service, using the services’ default settings except for the confidence threshold, which is configured in our workflow.

We obtained optimal thresholds for each system (Column i in Tables 1 and 2) with the BAT Framework7 (Cornolti et al., 2013). The BAT Framework allows calling several entity linking tools and compares their results using different annotation confidence thresholds, with a view to finding the thresholds that yield best results according to several evaluation measures.

Annotations are filtered out if their confidence is below the thresholds obtained in the way just described. The remaining annotations proceed to the annotation-voting step.

3.2 Pre-ranking Annotators

Our annotation voting exploits annotators’ precision on an annotated reference set in order to weight the annotations produced by each annotator (details in 3.3 below). It is not viable to create a reference set for each new corpus that we need to perform entity linking on. To help overcome this issue, we adopt the following approach: We have ranked the annotators for precision on two reference sets: AIDA/CONLL Test B (Hoffart et al., 2011), and IITB (Kulkarni et al., 2009). The IITB dataset contains annotations for category Others, i.e. entities that are not a person, organization or location, whereas AIDA/CONLL B does not contain such annotations. The proportion of annotations in a corpus that fall into the Others category is a strong predictor of annotators’ performance on that corpus, according to a study on how different dataset features correlate with annotators’ results, available on the GERBIL platform8 (Usbeck et al., 2015). Taking this into account, in order to annotate a new corpus, if annotations for the Others category are needed for that new corpus, the annotator ranking for the IITB corpus will be used in order to weight the new corpus’ annotations, since IITB is the only one among our two reference sets that contains annotations for Others, and an annotator performing well on IITB is likely to perform well when annotations for Others are needed. If, conversely, annotations for the Others category are not needed, the annotator ranking for the AIDA/CONLL B reference corpus is used in order to weight the new corpus’ annotations.

3.3 Annotation Voting Scheme

The voting scheme is in Figure 1. Each annotation is formalized as a pairing between a mention m (a span of characters in the text) and a Wikipedia entity e. For each annotation <m, e>, Ωm is the set of annotations whose mentions overlap9 with m. The set Ωm is divided into disjoint subsets, each of which contains annotations linking to a different entity. Each subset L is voted by vote(L): For each annotation o in L, N is the number of annotators we combine (i.e. 5), r_o,amr, is the rank of annotator amr, which produced annotation o, and P_o is amr’s precision on the ranking reference corpus (see 3.2 above). Finally, parameter α influences the distance between the annotations’ votes based on their annotators’ rank, and was set at 1.75 based on the best results on both ranking reference corpora.

4 https://github.com/yago-naga/aida
5 http://babelfy.org/download.jsp
6 The public deployments were used, but for AIDA, which was set up locally: Source v2.1.1, Data 2010-08-17v7. In AIDA, the tech=GRAPH option was used (non-default, but recommended by AIDA’s authors for benchmarking).
7 https://github.com/marcocor/bat-framework
8 See Annotator - Dataset feature correlations at http://gerbil.aksw.org/gerbil/overview
9 Assume two mentions (p1, e1) and (p2, e2), where p1 and p2 are the mentions’ first character indices, and e1 and e2 are the mentions’ last character indices. The mentions overlap iff (p1 = p2) ∧ (e1 = e2) ∨ ((p1 = p2) ∧ (e1 < e2)) ∨ ((p1 = p2) ∧ (e2 < e1)) ∨ ((e1 = e2) ∧ (p1 < p2)) ∨ ((e1 = e2) ∧ (p2 < p1)) ∨ ((p1 < p2) ∧ (p2 < e1)) ∨ ((p2 < p1) ∧ (p1 < e2)).
for each set $\Omega_m$ of overlapping annotations:

for $L \in \Omega_m$:

$$\text{vote}(L) = \frac{\sum_{o \in L} \left( N - (r_{o, anr} - \alpha) \right) \cdot P_{o, anr}}{N}$$

if $\max_{L \in \Omega_m} (\text{vote}(L)) > P_{\max}$ then

select $\arg\max_{L \in \Omega_m}(\text{vote}(L))$

Figure 1: Entity voting scheme.

The entity for the subset $L$ which obtains the highest vote among $\Omega_m$ ’s subsets is selected if its vote is higher than $P_{\max}$, i.e. the maximum precision for all annotators on the ranking corpus. Once an entity has been selected for a set of overlapping mentions, the mention itself needs to be selected. Best results were obtained when the most common mention in the set was selected. In case of ties, the longest mention among the most common ones was selected (e.g. if two mentions occur twice each in the set, select the longer one).

4 Evaluation and Results

4.1 Evaluation Method

Datasets: The workflow was tested on four golden sets. First, the two datasets that had also been used as reference sets in order to obtain the weights to vote annotations with (see Section 3.2). These two datasets were AIDA/CONLL B (231 documents with 4485 annotations; 1039 characters avg., news and sports topics) and IITB (103 documents with 11245 annotations; 3879 characters avg., topics from news, science and others). In order to test whether the annotator weights obtained from those two corpora can improve results when applied to annotator combination on other corpora, we tested on two additional datasets: MSNBC (Cucerzan, 2007), with 20 documents and 658 annotations (3316 characters avg., news topics) and AQUAINT (Milne and Witten, 2008b), with 50 documents and 727 annotations (1415 characters avg., news topics).

The AQUAINT dataset contains annotations for common noun entities (besides Person, Location, Organization). For this reason, according to the procedure described in 3.2 above, its annotations were weighted according to annotators’ ranking on the IITB corpus, which also contains common-noun annotations. The MSNBC dataset does not contain common-noun annotations, so the annotator ranking for the AIDA/CONLL test-set was used in order to combine annotations in MSNBC.

Measures: The EL literature has stressed the importance of evaluating systems on more than one measure. We tested the workflow on strong annotation match (SAM) and entity match (ENT) (Cornolti et al., 2013). SAM requires an annotation’s position to exactly match the reference, besides requiring the entity annotated to match the reference entity. ENT ignores positions and only evaluates whether the entity proposed by the system matches the reference.

Mapping files: Evaluating EL to Wikipedia requires making sure that we consider the same set of target entities for each EL system, since the versions of Wikipedia deployed within each system may differ. A mapping between current Wikipedia titles for the golden set annotations and non-canonical forms for these titles was created (including e.g. older titles redirecting to the new ones), and applied to golden and system sets before evaluation.

Tools: Evaluation was carried out with the neleval tool from the TAC-KBP Entity Discovery and Linking task (Ji et al., 2014). The tool implements several EL-relevant metrics, accepting a common delimited format for golden sets and results across corpora. The tool’s significance testing function via randomized permutation/bootstrap methods was also applied to our results.

4.2 Results and Discussion

Results are provided in Table 1 (SAM measure) and Table 2 (ENT measure). Note that, to promote transparency, individual system annotations, combined results, reference annotations and mapping files are available on a website. Each table shows micro-averaged precision, recall and F1 on the four golden sets, for each individual system, plus results for the combined workflow in the last row. The optimal confidence thresholds for each annotator are also indicated where applicable.

---

10 See Table 1 and Table 2 below for $P_{\max}$ values in the ranking reference corpora: $P_{\max}$ is the maximum (excluding row Combined) in columns AIDA/CONLL B and IITB.

11 The mapping was created based on fetch_map from the conll03_nel_eval tool by Hachey et al. (2013), https://github.com/wikilinks/conll03_nel_eval

12 https://github.com/wikilinks/neleval/wiki

13 https://sites.google.com/site/entitylinking1/
The combined workflow was able to improve over the best individual system regardless of which this system was: Tagme, Wikipedia Miner or AIDA. In some cases, the improvements over the best individual system’s F1 take place because of markedly increased recall in the combined system compared to the best individual system’s recall, without a major decrease in precision in the combined system (see AQUAINT results for ENT). The opposite pattern of improvement is also attested: In the MSNBC results for SAM, it is the increased precision of the combined workflow that makes its F1 improve over the best individual system’s F1.

Regarding the significant drop in F1 in the combined system vs. the best individual system (AIDA) in the ENT results for the AIDA/CONLL B corpus, note that, in this case, the difference between AIDA’s individual results and the results for the second-best individual system was much higher (17.2 points of F1) than anywhere else in the rest of tests performed. When such a large difference exists between the best individual system and the rest, an alternative type of voting may be needed in order to improve results over the best individual system.
5 Conclusion and Future Work

A workflow that combines the outputs of public open source entity linking (EL) systems via weighted voting was presented. The simple voting scheme generally improved F1 scores over the best individual system’s F1, as assessed by the strong annotation match and entity match measures. Besides some enhancements to the voting scheme, interesting future work could be comparing this simple scheme’s results with a more complex combination method, e.g. involving supervised learning based on available corpora annotated for entity linking (with mention–entity pairings).
