CHANNEL-AWARE ENERGY OPTIMIZATION OF OFDM RECEIVERS USING DYNAMIC PRECISION SCALING IN FPGAS

Fernando Cladera, Matthieu Gautier and Olivier Sentieys

University of Rennes 1, IRISA, INRIA, France

ABSTRACT

To reduce the energy consumption of Orthogonal Frequency-Division Multiplexing (OFDM) systems, a new variable word-length method is presented in this paper. A simulation based approach is used: the optimized fixed-point implementation of an OFDM receiver is found for different simulated channel conditions, depending on the Signal-to-Noise Ratio (SNR) and the channel type. During the execution, the receiver estimates the channel conditions and chooses the optimum word-length to decode the received information. A realistic energy consumption of the receiver is estimated with a library that contains the energy consumption of Field-Programmable Gate Array (FPGA) basic operators depending on the bit-width, obtained from experimental data. Up to 57% of the dynamic energy can be saved using this method.

Index Terms— Fixed-point arithmetic, OFDM receiver, energy reduction, variable wordlength

1. INTRODUCTION

Wireless devices are ubiquitous nowadays. They are used not only for audio communications, but also new services (such as video streaming) are proposed. These services require high throughput, which leads to an inevitable rise of power consumption. Yet, wireless devices are often battery powered, hence low power consumption is required. This study focuses on wireless systems based on OFDM, which is a standard for a wide range of modern wireless devices (e.g. LTE, 802.11a/g/n, DVB, DAB). The main advantage of OFDM systems is the high immunity to interferences, especially in the case of multipath channels [1].

Fixed-point arithmetic is favored to implement algorithms in embedded systems. Fixed-point operators are faster and use less area and energy. Memory and bus sizes are smaller too [2]. The fixed-point implementation is chosen during the development of the architecture, using analytical or simulation approaches. For both cases hypotheses are made about the system’s working conditions, which influence the resulting word-length of the implementation. Therefore, multiple conditions may imply different fixed-point implementations.

In a static fixed-point wireless receiver, data and operator bit-widths are chosen to deal with the worst condition. However, the system is oversized when better working conditions are present. In [3], Dynamic Precision Scaling (DPS) was introduced: multiple channel conditions are analyzed during the design phase and then, the best fixed-point implementations is chosen during the execution. [3] shows that an energy saving of 25% to 50% can be achieved in a WCDMA receiver.

In [4], a new variable adaptive word-length OFDM receiver was presented, reducing the energy consumption by 18% to 30%. Nonetheless, this technique leads to an unavoidable modification of the OFDM frame by the insertion of a search symbol. Thus, existing standards have to be modified. This technique was improved in [5], by using a Viterbi decoder. The Hamming distance for a maximum word-length receiver is compared with many reduced-precision implementations, to determine the minimum word-length which does not degrade the link. Yet, this method requires many iterative operations during the execution, consuming part of the energy saved. In [6], a dynamic OFDM receiver for software defined radios is presented. Intensive simulations are used to choose the right number of bits for the Fast Fourier Transform (FFT) depending on the SNR, saving 50% of the energy. The method used to optimize the receiver is similar to the one presented in this paper, but [6] does not specify how to switch between fixed-point implementations and only Additive Gaussian White Noise (AGWN) channels are analyzed. In [7], an analytical method to optimize the FFT block word-length is presented and applied to a DPS system. This method decreases significantly the time needed to find the fixed-point implementations for each channel condition. However, only AGWN channels are targeted, and the energy consumption when channel type varies is not analyzed. Important energy reductions can be achieved if the channel type is considered in the analysis of the word-length.

The contributions of this paper are the following: apply the DPS technique in an OFDM receiver, where a low complexity selector is used to choose the processing word-length at run time (without modifying the standard OFDM frame). Energy savings will be estimated with a library that contains the energy consumption of basic operators (such as adders and multipliers) depending on the bit-width, obtained from experimental data with FPGAs.

This paper is organized as follows: in Section 2, the OFDM receiver and the energy saving strategy will be presented. The energy consumption estimation of the receiver is also tackled. In Section 3, the fixed-point OFDM model and the fixed-point implementation selector are presented. In Section 4 the DPS architecture is simulated and the results are commented. Finally, Section 5 draws conclusions.

2. SYSTEM MODEL

2.1. Floating-Point Model of the OFDM Receiver

A frame-based OFDM receiver was proposed for this study with the following parameters: 16-QAM modulation, 512-point FFT (NFFT), 300 used subcarriers and 128-point Cyclic Prefix (Ncyc)\(^1\). At least one training symbol and ten OFDM symbols were used in an OFDM frame. In this study, the synchronization was supposed perfect and the equalizer coefficients were supposed known. Two channels were analyzed: an one-path AGWN and a Frequency Selective Fading (FSF) channel with AGWN. For both channels, the

\(^1\)These parameters have been set in order to emulate a 5 MHz long Cyclic Prefix LTE receiver.
Table 1. Energy consumed for arithmetic operations (adders and LUT multipliers) in a Virtex-5 FPGA (in [\(\mu\text{J}\)]).
The dynamic range (integer part) can be easily obtained using a simulation approach: for each channel type and SNR, multiple simulations using the floating point receiver are carried out. The data at each point where a quantizer will be placed is stored. Then, the number of bits that allows to represent the integer part of least 99.9% of the values is chosen for each quantizer.

However, obtaining the fractional part implies a much more complicated process: for every channel type and SNR, multiple simulations were executed using different fractional parts for each quantizer. Each precision implies a given BER, and the precision chosen is a tradeoff between the quality of the link and the energy spent during the reception. Fig. 3 shows an example of this process, where the energy consumption is related with the decoding quality, for different fractional sizes at each quantizer. Each point represents a different fixed-point implementation of the receiver, with an associated BER and energy consumption. The total energy consumed for a specific solution can be estimated using the data from Section 2.3, knowing the number of operators. The FFT needs $13 \times 10^3$ real additions and $9 \times 10^3$ real multiplications for this receiver, whereas the equalizer needs 600 real additions and 1200 real multiplications. The less consuming solution that respects a BER of $10^{-3}$ is chosen.

Fig. 4 shows the energy consumed for each optimized fixed-point solution, depending on the channel conditions. Some preliminary conclusions can be drawn: in the worst case, the energy needed to process an OFDM symbol is 291.05 $nJ$, while the best case needs only 74.56 $nJ$. Up to 74% of the energy can be saved using an adaptive receiver. Also, the fixed-point selector has to consider both the SNR and the channel type to calculate the performance metric $p$, used to select one of the five fixed-point implementations.

3.2. Fixed-Point Implementation Selector

Section 3.1 shows that the fixed-point implementations depends not only on the SNR but also on channel type. Thus, both parameters have to be estimated to select the appropriate fixed-point implementation. Estimators will be updated with each new symbol received.

3.2.1. SNR estimation

The estimator from [11] was used due to its simplicity. The SNR is calculated as:

$$ SNR = \frac{\sigma_d^2}{\sigma_n^2} = \left( \frac{y_{acc,\max}}{y_{acc,\min}} \right)^2 - 1, \quad (1) $$

where $\sigma_d^2$ is the power of the desired signal and $\sigma_n^2$ is the power of the noise. $y_{acc,\max}$ and $y_{acc,\min}$ correspond to a sum of $N_{acc}$ points after subtracting the signal delayed $N_{FFT}$ to the current symbol (minimum and maximum values respectively). In this work, the sum is made from the end to the beginning of the Cyclic Prefix (CP), to avoid the effects of multipath channels. For instance, to calculate $y_{acc,\max}$ the following operation is made:

$$ y_{acc,\max} = \sum_{N_{cyph} - N_{acc}}^{N_{cyph}} |x_{\text{subt}}| \quad (2) $$

$$ = \sum_{N_{cyph} - N_{acc}}^{N_{cyph}} \sqrt{\Re(x_{\text{subt}}^\max)^2 + \Im(x_{\text{subt}}^\max)^2}, \quad (3) $$

where $x_{\text{subt}}^\max$ is the complex signal after the subtraction. The equivalent equation can be written for $y_{acc,\min}$ using $x_{\text{subt}}^\min$.

Given that the calculation of the absolute value requires a square root, which is complex operation in embedded devices, the following modification is proposed:

$$ y_{acc,\max^*} = \sum_{N_{cyph} - N_{acc}}^{N_{cyph}} |x_{\text{subt}}^\max|^2 \quad (4) $$

$$ = \sum_{N_{cyph} - N_{acc}}^{N_{cyph}} \Re(x_{\text{subt}}^\max)^2 + \Im(x_{\text{subt}}^\max)^2 \quad (5) $$

$$ y_{acc,\min^*} = \sum_{N_{cyph} - N_{acc}}^{N_{cyph}} |x_{\text{subt}}^\min|^2 \quad (6) $$

$$ = \sum_{N_{cyph} - N_{acc}}^{N_{cyph}} \Re(x_{\text{subt}}^\min)^2 + \Im(x_{\text{subt}}^\min)^2 \quad (7) $$

$$ SNR^* = \frac{y_{acc,\max^*}}{y_{acc,\min^*}} - 1 \quad (8) $$
The number of points \( N_{\text{acc}} \) is chosen to target a specific detection error. In this study, we use all the available points of the CP which have not been affected by the multipath channel. Therefore, \( N_{\text{acc}} = 90 \) points were used to estimate the SNR.

The number of operations needed is 721 real additions, 360 real multiplications and one division. Using a fixed word-length (12-bit), the energy consumed by the SNR estimator is \( 35.01 \) nJ per OFDM symbol.

### 3.2.2. Channel Type Estimation

The variance of the equalizer coefficients was used as an indicator of the channel type. Indeed, in AGWN channels, equalizer coefficients are flat, whereas in FSF channels the coefficients show peaks and depressions. The estimator is given by:

\[
\hat{\theta} = \frac{1}{N} \sum_{i=1}^{N} (eq_i - \bar{eq})^2,
\]

(9)

where \( eq_i \) are the absolute values of the coefficients of the equalizer and \( \bar{eq} \) is the mean of \( eq_i \). \( \frac{1}{N} \) is a constant that can be eliminated, changing the detection threshold of the estimator.

In order to avoid the calculus of the absolute value (because of the square root), the following modification is proposed:

\[
\hat{\theta}^* = \sum_{i=1}^{N} \left| eq_i^2 - \bar{eq}^2 \right|.
\]

(10)

In addition, the equalizer coefficients are undersampled in order to reduce the number of calculations:

\[
\hat{\theta}^{**} = \sum_{i=nK} \left| eq_i^2 - \bar{eq}^2 \right|, \quad n = 1, 2, ...
\]

(11)

The undersampling \( K \) is chosen to have a specific detection error. In this paper, 75 points are needed to distinguish between different channel types\(^4\). Thus, 300 real additions, 150 real multiplications and 1 real division are needed for this estimator. Using a fixed word-length (12-bit), the energy needed is \( 15.10 \) nJ per OFDM symbol.

### 4. PERFORMANCE RESULTS

#### 4.1. Selector Performance

One of the keys for the correct behaviour of the dynamic receiver is an accurate fixed-point implementation selector. After simulating both estimators presented in Sec. 3.2, some results are presented in this section.

The SNR estimator presents some wrong detections during the execution. Fig. 5 shows the ratio of missed SNR estimations, depending on the channel type and SNR. The number of points for SNR estimation \( N_{\text{acc}} = 90 \) was chosen to have a ratio of \( 10^{-3} \) approximately. Experimentally, the average ratio fluctuates between \( 10^{-2.8} \) for the AGWN channel and \( 10^{-2.5} \) for the FSF channel.

\(^3\)For the sake of simplicity, one division is considered equivalent to ten multiplications.

\(^4\)In our receiver, the equalizer coefficients are presumed known. Nonetheless, the channel type estimator was calibrated using a Normalized Linear Mean Squares (NLMS) equalizer, implemented in a floating point receiver.

The channel type estimator is very accurate with 75 points. Fig. 6 shows the ratio of missed channel type estimations, for the FSF channel. Indeed, due to the fact that equalizer coefficients are known, this estimator is very accurate for AGWN channels. The average probability of miss-detection using 75 points is \( 10^{-2.8} \) approximately for the FSF channel.

Even if the quality of the SNR estimator seems low for the target BER, this does not mean that the receiver is not working correctly. Indeed, some erroneous SNR detections do not imply a degradation of the link because similar bit-widths may be used.

#### 4.2. DPS Performance

Our fixed-point OFDM receiver is combined with the selector, and 1000 simulations have been carried out for each channel condition in order to analyze its behavior. The BER-SNR curve is presented in Fig. 7. Dotted lines correspond to a static receiver using the “worst case” approach, whereas full lines correspond to the dynamic receiver using adaptive precision. It can be observed that for BER \( > 10^{-3} \) both curves are overlapped. But, when BER \( < 10^{-3} \) our adaptive system tries to follow the reference value while the static receiver decreases continuously its BER. For the AGWN channel, a superlative quality is reached for high SNR. This is due to the discrete

nature of fixed-point data: the implementation which can achieve the objective BER has this excessive quality.

Tab. 2 shows the energy consumption of the dynamic receiver, with its implementation selector. Comparing the energy consumption of this solution with the “worst case” approach, some conclusions are obtained. The maximum energy saving is approximately 57%. The upper bound defined in Section 3.1 is reduced due to the consumption of the selector. However, when working in FSF channels, the consumption of our receiver is slightly higher: 117% for low SNR values and 113% for high SNR values. These results may be improved if the selector uses less energy. For example, calculating the SNR using fewer symbols of the frame.

5. CONCLUSION

In this paper, a low power OFDM receiver is developed using DPS. An OFDM receiver is presented, and a procedure to find the appropriate word-length is shown (based on intensive simulations). Results show that the word-length depends not only in the noise level, but also on the channel type. Thus, a low-power selector to switch between the different fixed-point implementations was developed. The energy consumption of the receiver is calculated using a library obtained from our experimental data, knowing the number of operators and the word-length. Compared to the state of the art [4] [5] [6] [7], the OFDM frame is not modified in this method and the introduction of a search symbol is not needed to estimate the channel conditions. Our solution can save up to 57% of the energy, targeting an objective BER of $10^{-3}$.
