THE "ALAAS" AND THE STOCK FARMING IN YAKUTIA

A sub-arctic pastoral system based upon cryogenic wetlands

Salleron G., Météallé J.-P. University of Toulouse, GEODE-CNRS, France

The agriculture of Yakutia (Sakha republic) is characterized by a breeding of cows and horses in extreme climatic conditions. The pastoral zones are located between 60° and 65°N, in an area of Siberia with very strong continental subarctic climate. At Yakutsk (62° 05' N. 129°45'; 103 m a.s.l.), the mean annual temperature is -16.0°C, and mean monthly temperatures in January and July are -41.2°C and 18.7°C, respectively. Mean annual precipitation is 237 mm (National Astronomical Observatory, 2001), of which 130mm in summer.

Permafrost is present in all the territory and thickness can reach 500 m near Yakutsk, in central Yakutia the melting of permafrost in summer can reach a depth of 2-3 meters in sunny conditions, but only 50 cm in cold places (northern exposures and under forests). The geology of centre Yakutia is mainly of quaternary loess deposits covering the alluvial terraces of Lena and Aldan rivers.

The vegetation of alasas is closely dependent of thermokarstic morphology and climatic conditions: the presence of lakes and stagnate water, and the fluctuation of the water level create complex zones of herbaceous vegetation. In the center of the alasas or around the lakes, temporary marshes dominate with Carex and Scirpus; a second ring corresponds to the rich meadows which can be mown and provide the great quantity of hay necessary for the winter. In the peripheral areas, the soils are dry and saline, and the vegetation is dominated by the Artemisia steppe, which can be only grazed. In the sunny woods of larch (Larix Gmelini) and birches, the cattle can also find some grass in the underwood and in the burned stands; on the opposite, in the northern exposures and in the dense forests, the permafrost remains superficial and the soil is covered only by lichens.

The alasas are thermokarstic depressions distributed throughout the central Yakutia. They are formed by thermal disturbance of the ice-rich permafrost surface and an increase in depth of the active layer (annually freezing thawing layer). The alasas, of circular forms, range in size from ca. 0.1 to 20 km in diameter, and 3 to 20 m in depth; the first stage of alasas process, a very active small lake depression, is locally named slavok. The dunes are very numerous in the forest areas. In the lowland of central Yakutia, approximately 20% of land area is covered with alasas but the density is very variable.

In the valley of the Taiga river, the classification of the Landsat image show the great number and extension of the alasas, which allows a good availability of meadows and hay. This region has been still today one of the main centers of the Yakut stockbreeding.

Sakhas, or Yakuts, are stockbreeders of horses and cows; they are of Turco-Mongolian origin and would have colonized Yakutia during the Middle Ages. Towards 16th-17th centuries, by transplanting a stockbreeding adapted to less cold areas. From central Yakutia, they colonized more septentrional areas (Yenisei, Verkhoyansk), probably during 17th and 19th centuries. Traditionally, yakut stockbreeding is based upon stabulation of the cows during the long and very cold winter (9-10 months), and summer transhumance at short distance in the nearby pastures. The horses, very robust, stand outside during winter.

Until the Revolution, the yakuts lived in family hamlets in the middle of the pastures of the clan. The summer habitat was a "tappam" of Birch bark. During the soviet period, they were gathered in kholsozes and sarchozes, with great collective cowsheds and rustic Yakut cows were replaced by imported race (Simmental, Holstein). Agriculture and ploughing were intensified in the dry parts of the alasas and terraces, causing the degradation of the fragile soils. From the fall of communism, the yakuts reconstituted family farms in the villages and the alasas were allotted according to the number of family members. The interannual fluctuation of water level in the alasas does not allow the precise delimitation of an exploitable surface.

Because of this connection between thermokarstic process and dynamics of the vegetation, it is probable that the floder resource of the alasas persisted on arrival of the first Sakhas. One can make the hypothesis that the presence of this resource was one of the factors of the installation of these stockbreeders, which transported their cattle of regions distant from several thousands of kilometers. Indeed, the principal areas of historical Sakha settlement (like the valley of Taiga river, 100 km in the east of the Lena) are characterized by the abundance of the alasas and the associated pastures.

However, the studies attest of an increase in herbaceous vegetation during the last centuries, showing an impact of the yakut stockbreeders and an extension of the pastures in the surroundings of the natural alasas.
