Abstract
In this paper, we strengthen two recent undecidability results of [9,10] about weighted timed automata, an extension of timed automata with cost variables. More precisely, we propose new encodings of a Minsky machine that only require three clocks and one stopwatch cost, while they required five clocks and one stopwatch cost in [9,10].

Key words: Weighted timed automata, weighted timed games, undecidability

1 Introduction

Weighted timed automata (WTA for short), or priced timed automata, have been defined in 2001 independently by Alur et al. [5] and Larsen et al. [6] for modelling resource consumption in timed systems. They extend classical timed automata (TA) [3] with cost information on both locations and edges. These costs increase while time elapses, but are never tested in the automaton. An interesting problem is then to compute the optimal cost for reaching a given state. In [5,6], this problem (called optimal reachability) is proved decidable.

In order to express more involved properties, the logic WCTL has been proposed as an extension of TCTL [2] in which cost variables can be constrained [11]. Model-checking this logic is undecidable in general for the classical dense-time semantics [11,9]. Games played on WTAs with an optimality criterion have been considered in [12,1,7,10] and though partial decidability results have been obtained in [1,7], it has recently been proved in [10] that the general problem of finding optimal strategies in such a game is undecidable. In this paper, we improve both undecidability results mentioned above: our encodings are simpler, and above all, the reductions use only three clocks, instead of five in [9,10].

2 Preliminaries

In the sequel, $X$ is a finite set of clocks and $\text{AP}$ is a finite set of atomic propositions. We adopt standard notations for TAs and refer to [3] for classical definitions. A WTA is a tuple $(\text{Loc}, \text{Edg}, \text{Lab}, \text{cost})$ where $(\text{Loc}, \text{Edg}, \text{Lab})$ is a TA and cost: Loc $\cup$ Edg $\rightarrow \mathbb{N}$ is an extra cost function. A run of a WTA is a run of the underlying TA, having both continuous (time-elapsing) and discrete transitions. Given a run $\rho$ and a state $p$ along that run, we write $\rho[p]$ for the finite prefix of $\rho$ ending at $p$. Let $\rho$ be the finite run $(\ell_0, \alpha_0) \xrightarrow{\gamma_0} (\ell_1, \alpha_1) \xrightarrow{\gamma_1} (\ell_2, \alpha_2) \cdots \xrightarrow{\gamma_{k-1}} (\ell_k, \alpha_k)$ where $\gamma_i \in \mathbb{R}_+$ for continuous transitions and $\gamma_i \in \text{Edg}$ for discrete ones. We define

$$\text{cost}(\rho) = \sum_{i \leq k, \gamma_i \in \mathbb{R}_+} \text{cost}(\ell_i) \cdot \gamma_i + \sum_{i \leq k, \gamma_i \in \text{Edg}} \text{cost}(\gamma_i).$$

Our constructions only involve one cost, we thus always have $d = 1$ in the sequel. A stopwatch cost is a cost $\text{cost}$ s.t. $\text{cost}(\text{Loc}) \subseteq \{0, 1\}$.

We consider the logic $\text{WCTL}^1$, a branching-time logic close to $\text{TCTL}$ [2] and $\text{ICTL}$ [4]. It is built over $\text{AP}$ with boolean combinators, and with two families of modalities $\text{E U}_{\sim c}$ and $\text{A U}_{\sim c}$, where $\sim \in \{<, \leq, =, >, \geq\}$, and $c \in \mathbb{N}$. Let $\xi \in \text{WCTL}$, $\mathcal{A}$ be a WTA and $q$ be a state of $\mathcal{A}$. That $\xi$ holds in $\mathcal{A}$ at state $q$, denoted by $\mathcal{A}, q \models \xi$, is defined in the standard way for atomic propositions and boolean combinators, and by:

- $\mathcal{A}, q \models \text{E} (\varphi \text{ U}_{\sim c} \psi)$ iff there exists a run $\rho = (q_i)_{i \geq 0}$ in $\mathcal{A}$ with $q = q_0$, and a position $p$ in $\rho$ such that $\mathcal{A}, p \models \psi$ and $\text{cost}(\rho[p]) \sim c$ and $\mathcal{A}, p' \models \varphi$ for all positions $p'$ $\neq$ $p$ of $\rho[p]$;
- $\mathcal{A}, q \models \text{A} (\varphi \text{ U}_{\sim c} \psi)$ iff for any infinite run $\rho = (q_i)_{i \geq 0}$ in $\mathcal{A}$ with $q = q_0$, there exists a position $p$ in $\rho$ such that $\mathcal{A}, p \models \psi$ and $\text{cost}(\rho[p]) \sim c$ and $\mathcal{A}, p' \models \varphi$ for all positions $p'$ $\neq$ $p$ of $\rho[p]$.

In the sequel, we might omit to mention $\mathcal{A}$ when it is clear from the context, and simply write $q \models \varphi$.

3 Encoding the Counters

We now explain the undecidability proof for $\text{WCTL}$ model-checking. Let $\mathcal{M}$ be a two-counter machine [13]. We build a WTA $\mathcal{A}_{\mathcal{M}}$ (with three clocks and one stopwatch cost) and a $\text{WCTL}$-formula $\Phi$ such that given $q_0$, a well-chosen state of $\mathcal{A}_{\mathcal{M}}$, we have that $\mathcal{M}$ halts if, and only if, $q_0 \models \Phi$. The two counters $c_1$ and $c_2$ will be encoded alternately by three clocks $x$, $y$ and $z$. The value of $c_1$ is encoded by $x_1 = 1/2^x$ (with $x_1 \in \{x, y, z\}$) whereas the value of $c_2$ is encoded by $x_2 = 1/3^x$ (with $x_2 \in \{x, y, z\}$). To each instruction will be associated six modules, one for each injective function $\{x_1, x_2\} \rightarrow \{x, y, z\}$.

$^1$ WCTL stands for “Weighted CTL”.

2
3.1 Incrementation of a counter

We consider the following instruction of the two-counter machine:

\[ p_i : \; c_1 := c_1 + 1; \; \text{goto } p_j. \]

We also assume that the initial value of \( c_1 \) is stored in clock \( x \) whereas that of \( c_2 \) is stored in \( y \). To \( p_i \), we associate the automaton \( \text{Aut}_{1,+}^i(x,y,z) \) as in Fig. 1. In that figure (and in all the other ones), costs which are omitted are equal to zero. The subscript \( 1,+ \) is a remainder that instruction \( p_i \) deals with counter stored in the first clock (\( x \) here) and is an incrementation (we might omit it when it is not necessary), the tuple \((x,y,z)\) indicates which clocks encode counters \( c_1 \) and \( c_2 \): here, \( c_1 \) is initially stored in \( x \) and \( c_2 \) is initially stored in \( y \). At the end of this module, the new values of \( c_1 \) and \( c_2 \) are stored in \( z \) and \( y \), resp.; that’s why we swap \( x \) and \( z \) when leaving the module (transition from \( D^i_{x,y,z} \) to \( A^j_{z,y,x} \)).

![Fig. 1. Automaton \( \text{Aut}_{1,+}^i(x,y,z) \)](image)

For that automaton to really increment the first counter, we will enforce the following requirements (see Section 5): (1) the delay between arrival in \( A^i_{x,y,z} \) and arrival in \( D^i_{x,y,z} \) is 1 t.u., (2) when entering \( D^i_{x,y,z} \), \( z \) equals \( x/2 \) and (3) the delay elapsed in \( D^i_{x,y,z} \) is 0.

The last point will be ensured through a global WCTL-formula stating that no cost is accumulated in location \( D^i_{x,y,z} \). The second point is obtained by a module \( \text{Test}(x=2z,\{y\}) \), together with a WCTL-formula \( \varphi_1 \) (see Section 4.2 for details on that module). Finally, according to Lemma 1 below, the first point is enforced by checking that the values of \( x \) and \( y \) when entering \( D^i_{x,y,z} \) are \( 1/2^n \) and \( 1/3^m \) for some integers \( n \) and \( m \). Those conditions are ensured by modules \( \text{Power}_2 \) and \( \text{Power}_3 \) and the associated formulas \( \varphi_2 \) and \( \varphi_3 \), whose construction is explained in Section 4.3.

**Lemma 1** If a run enters location \( A^i_{x,y,z} \) with \( x = 1/2^{c_1} \), \( y = 1/3^{c_2} \) and enters location \( D^i_{x,y,z} \) \( t \) time units later with the value of \( x \) of the form \( 1/2^n \) for some \( n \), and the value of \( y \) of the form \( 1/3^m \) for some \( m \), then \( t = 1 \), \( n = c_1 \) and \( m = c_2 \).

This lemma can easily be proved using elementary arithmetical manipulations. It plays a crucial role in our reduction: it explains how comparing clocks to powers of \( 1/2 \) and \( 1/3 \) gives a way to measure exactly 1 t.u., and thus why we encode the counters as powers of \( 1/2 \) and \( 1/3 \). Note that \( 2 \) and \( 3 \) could be replaced by any two relatively prime numbers.
Similar ideas can be used for designing an automaton $\text{Aut}_{2,+}^i(x, y, z)$ that increments the second counter (i.e., ends up with $z = y/3$, while $x$ returns to its original value), involving module $\text{Test}(x = 3z, \{y\})$.

### 3.2 Decrementation of a counter

We now treat instruction: $p_i : \text{if } (c_1 > 0) \text{ then } c_1 := c_1 - 1 \text{; goto } p_j \text{ else goto } p_k$. We only give the construction of automaton $\text{Aut}_{1,-}^i(x, y, z)$, which is a slight variation of the previous construction. This automaton implements the decrementation of the first counter, initially stored in $x$, unless it equals zero.

In the global reduction, we will enforce the following properties: (1) the values of $x$ and $y$ when entering $D_{x,y,z}^j$ are $1/2^n$ and $1/3^m$ for some $n$ and $m$, (2) when entering $D_{x,y,z}$, $z$ equals $2x$ and (3) the delay in $D_{x,y,z}$ is 0. As previously, we can prove that these three conditions express correctness of the construction. Lemma 1 clearly also holds for $\text{Aut}_{1,-}^i(x, y, z)$. Automaton $\text{Aut}_{2,-}^i(x, y, z)$ is built in the same way.

### 4 Modules

#### 4.1 Adding $x$ or $1 - x$ to the cost variable, where $x$ is a clock

Following [10], we build modules $\text{Add}^+(x, \{z\})$ and $\text{Add}^-(x, \{z\})$, displayed on Fig. 3 and 4. Those automata clearly satisfy the following Lemma:

**Lemma 2** If a run enters location $\ell_0$ of $\text{Add}^+(x, \{z\})$ (resp. $\text{Add}^-(x, \{z\})$) with $x = \alpha_0 \in [0, 1]$, $y = \beta_0 \in [0, 1]$ and $\text{cost} = \gamma_0$, it then leaves location $\ell_1$ with the same values for $x$ and $y$, and with $\text{cost} = \gamma_0 + \alpha_0$ (resp. $\text{cost} = \gamma_0 + 1 - \alpha_0$).

#### 4.2 Checking $y = 2x$

Module $\text{Test}(y = 2x, \{z\})$ is the (deterministic) automaton displayed on Fig. 5. It sets the cost to $2x + 1 - y$. Let $\varphi_1 = S \land EF \leq 1 T \land EF \geq 1 T$. The following Lemma clearly holds:

![Fig. 2. Automaton $\text{Aut}_{1,-}^i(x, y, z)$](image-url)
Lemma 3 Formula \( \varphi_1 \) holds in \( S \) along module \( \text{Test}(y = 2x, \{z\}) \) with \( x = \alpha_0 \in [0,1] \) and \( y = \beta_0 \in [0,1] \) if, and only if, \( \beta_0 = 2\alpha_0 \).

This construction can easily be adapted for other tests, especially for building a module \( \text{Test}(y = 3x, \{z\}) \) testing if \( y = 3x \).

### 4.3 Checking that the value of \( x \) is of the form \( 1/2^d \)

Module \( \text{Power}_2(x, \{y,z\}) \) is displayed on Fig. 6. Note that it requires two auxiliary clocks. Note also that it uses an update “\( x := y \)” instead of classical resets. This is for the sake of simplicity, as the module could be adapted (by duplicating the periodic part, involving no extra clock) in order to only have standard resets [8].

We let \( \varphi_2 = P_2 \land \mathbf{E} ((Q_2 \rightarrow \mathbf{E} (Q_2 \mathbf{U} \varphi_1))) \mathbf{U} R_2 \). We have the following Lemma:

Lemma 4 Formula \( \varphi_2 \) holds in \( P_2 \) in module \( \text{Power}_2(x, \{y,z\}) \) with \( x = \alpha_0 \in (0,1] \) if, and only if, there exists a non-negative integer \( d \) s.t. \( \alpha_0 = 1/2^d \).

**PROOF.** Let \( q_0 \) be the configuration \( (P_2, \langle \alpha_0, -, 0 \rangle) \) when entering \( P_2 \) for the first time. Assume that \( \text{Power}_2(x, \{y,z\}), q_0 \models \varphi_2 \), and pick a run \( \rho \) witnessing this property, i.e., starting from \( P_2 \), reaching \( R_2 \), and s.t. intermediate positions satisfy \( Q_2 \rightarrow \mathbf{E} (Q_2 \mathbf{U} \varphi_1) \) in \( \text{Power}_2(x, \{y,z\}) \). Since time cannot elapse in \( Q_2 \), Lemma 3 ensures that, when entering \( Q_2 \), the value of \( y \) is always twice the value of \( x \).

Let \( n \) be the number of times \( \rho \) enters the location \( Q_2 \). If \( n = 0 \), then \( \alpha_0 = 1 = 2^0 \), as required. Now, assume \( n > 0 \). Clearly, clock \( x \) has the same value when \( \rho \) enters \( Q_2 \)
as the previous time it entered $P_2$, provided this value is in $(0,1]$. Since $y = 2x$ when entering $Q_2$, it can easily be proved by induction that, when entering $Q_2$ for the $k$-th time, with $k \leq n$, then $x = 2^{k-1} \alpha_0$. Thus, the last time run $\rho$ enters $Q_2$, we have $x = 2^{n-1} \alpha_0$, and $y = 2^n \alpha_0$. From that point on, $\rho$ must go to location $R_2$ without entering $Q_2$ any more. This requires that the last value of $y$ in $Q_2$ is 1. Thus $\alpha_0 = 1/2^n$.

Conversely, if there exists a non-negative integer $d$ s.t. $\alpha_0 = 1/2^d$ we have to prove that $\text{Power}_2(x, \{y, z\}, q_0) \models \varphi_2$. We build by induction a run $\rho_d$ witnessing this fact. If $d = 0$, we take $\rho_d = (P_2, (1, -), 0) \rightarrow (R_2, (1, -), 0)$. Otherwise, assume we can build a run $\rho_{d-1}$ from $(P_2, (1/2^{d-1},-,0))$ to $(R_2, (1, -), 0)$. We build $\rho_d$ as follows:

Clearly, the paths $\rho_d$ are paths of $\text{Power}_2(x, \{y, z\})$ and satisfy $\varphi_2$. □

It is easy to adapt this construction in order to build a module $\text{Power}_3(x, \{y, z\})$ and a formula $\varphi_3$ that check if $x$ is of the form $1/3^d$, for some integer $d$.

5 Global Reduction

We build the global automaton $A_M$ inductively using sub-automata $\text{Aut}_{\text{c},+}^i$ and $\text{Aut}_{\text{c},-}^i$ as explained previously. To the halting instruction corresponds a unique location $A_{\text{Halt}}$, labelled with $\text{Halt}$. The initial location is the state $A_{x,y,z}^1$ denoted $A^1$ for short. In the sequel, a state of $A_M$ is written $(A, (x, y, z))$, where $A$ is the location and $(x, y, z)$ is the valuation of $x$, $y$ and $z$, in that order. Thus, the initial configuration of $M$ is encoded by $q_0 = (A^1, (1, 1, 0))$. We set a new atomic proposition $D$ which is true in all states $D_{\sigma(x,y,z)}^i$, for any permutation $\sigma$.

As explained in Section 4, our modules ($\text{Test}$, $\text{Power}_2$ and $\text{Power}_3$) require that some WCTL formulas (namely $\varphi_1$, $\varphi_2$ and $\varphi_3$) hold in their initial state in order to really play their roles. This will be ensured in $A_M$ through the following formula: $\Phi = \text{E} [(D \rightarrow \varphi) \ U_{\leq 0} \ \text{Halt}]$ where $\varphi = \bigwedge_{i=1,2,3} \text{E} (D U_{\leq 0} \varphi_i)$.

Lemma 5 $A_M, q_0 \models \Phi$ iff the two-counter machine $M$ has a halting computation.

Proof. First assume $q_0 \models \Phi$, and pick a run $\rho$, starting in $q_0$ and witnessing $\Phi$, i.e., reaching state $\text{Halt}$ with cost 0, and such that intermediate positions satisfy $D \rightarrow \varphi$ in $A_M$. As the cost rate in all $D$-states is 1, and the overall cost of $\rho$ is 0, no time can elapse in $D$-state. Also, each time $\rho$ is in a $D$-state, $\varphi$ holds. Consider a $D$-state $(D_{x,y,z}^i, (x_D, y_D, z_D))$ along $\rho$ (the case of other permutations of $(x, y, z)$ would be treated similarly). In that state:

- formula $\text{E} (D U_{\leq 0} \varphi_2)$ holds, where $\varphi_2 = P_2 \land \text{E} ((Q_2 \rightarrow \text{E} (Q_2 U \varphi_1)) U R_2)$ (see Section 4.3). This means that this is possible to immediately enter module
Power\textsubscript{2}(y,\{y, z\}) and satisfy \(\varphi_2\). Lemma 4 then ensures that \(y_D\) equals \(1/2^n\), for some integer \(n\).

- similarly, formula \(E(DU_{\leq 0} \varphi_3)\) and module \(Power_3(x,\{y, z\})\) ensure that \(x_D\) equals \(1/3^m\) for some integer \(m\).
- formula \(E(DU_{\leq 0} \varphi_1)\) holds, where \(\varphi_1 = S \land E F_{\leq 1} T \land EF_{\geq 1} T\) (see Section 4.2).

Thus, it is possible to immediately (with clock values \(y_D, x_D\) and \(z_D\)) enter module \(Test(y = 2z, \{x\})\) (or another \(Test\) module, depending on instruction \(i\)) and satisfy \(\varphi_1\). According to Lemma 3, this ensures that the corresponding test holds, i.e. \(y_D = 2z_D\) (for the case of \(Test(y = 2z, \{x\})\)).

It follows that:

- if \(\rho\) enters \(Aut_{1,+}^i(y, x, z)\), say, with clock valuation \((1/3^m, 1/2^n, -)\), then, according to Lemma 1 (whose hypotheses hold, according to the remarks above), it reaches \(D_{y,x,z}^i\) (and then the next sub-automaton \(Aut^j(z, x, y)\) after exactly 1 t.u. with clock valuation \((1/3^m, -1/2^{n+1})\).

- if \(\rho\) enters \(Aut_{1,-}^i(y, x, z)\) with \(y = 1\), then it immediately enters the next sub-automaton, without letting time elapse.

- if \(\rho\) enters \(Aut_{1,-}^i(y, x, z)\) with valuation \((1/3^m, 1/2^n, -)\), assuming \(n \neq 0\), then we can again apply Lemma 1, which claims that \(\rho\) reaches \(D_{y,x,z}^i\) (and then the next automaton \(Aut^j(z, x, y)\)) after exactly 1 t.u. and with valuation \((1/3^m, -1/2^{n-1})\).

By induction, whenever \(\rho\) enters the first location of a sub-automaton \(Aut^i(\alpha, \beta, \gamma)\), for any permutation \((\alpha, \beta, \gamma)\) of \((x, y, z)\), then \(\alpha = 1/2^n\) and \(\beta = 1/3^m\), for some integers \(n\) and \(m\). According to \(\Phi\), \(\rho\) eventually enters state \(A_\text{Halt}\). In the meantime, it traverses a (finite) sequence \((A_k)_k\) of sub-automata of the form \(Aut^i(\alpha, \beta, \gamma)\). Thus, to \(\rho\), we can associate a sequence of tuples \(p_k = (i_k, c_{1,k}, c_{2,k})\) as follows:

(a) \(i_k\) is the index \(i\) of the sub-automaton \(A_k\), (b) \(c_{1,k}\) is the integer s.t. \(\alpha = 1/2^{c_{1,k}}\) when \(\rho\) enters \(A_k\), and (c) \(c_{2,k}\) is the integer s.t. \(\beta = 1/2^{c_{2,k}}\) when \(\rho\) enters \(A_k\).

Quite obviously, our construction ensures that the values of the counters between \(p_k\) and \(p_{k+1}\) are updated according to instruction \(i_k\) of \(M\). The sequence \((p_k)_k\) thus corresponds to a halting computation of \(M\).

Conversely, if \(M\) has a halting computation, we can exactly mimic this computation with a run in \(A_M\). The arguments are similar to the ones above in order to prove that this run satisfies \(\Phi\).

□

Theorem 6 Model-checking WCTL on WTAs with three clocks and one stopwatch cost is undecidable.

Note that our reduction holds for a restriction of WCTL not involving equality-constraints, and involves only a stopwatch cost.

6 Application to Optimal Reachability Timed Games

Optimal reachability timed games have been first introduced in [12] and further studied in [1,7,10]. We refer to the above papers for formal definitions.
A **weighted timed game** (WTG) is a WTA with a distinguished set of winning states, and where the set of actions is split into controllable actions (played by the controller) and uncontrollable actions (played by the environment). We assume a classical definition of strategies, and the aim of a game is, for the controller, to enforce winning states and to minimize the cost of the plays, whatever does the environment.

To illustrate these notions, we better give an example.

**Example 7 ([7])** We consider the WTG in Fig. 7. Dashed (resp. plain) arrows are for uncontrollable (resp. controllable) actions. Depending on the choice of the environment (going to location $\ell_2$ or $\ell_3$), the accumulated cost along plays of the game is either $5t + 10(2 - t) + 1$ (through $\ell_2$) or $5t + (2 - t) + 7$ (through $\ell_3$) when $t$ is the delay in state $\ell_0$. The optimal cost the controller can ensure is thus $\inf_{t \leq 2} \max(5t + 10(2 - t) + 1, 5t + (2 - t) + 7) = 14 + 1/3$, and the optimal delay is then $t = 4/3$. The optimal strategy for the controller is thus to wait in state $\ell_0$ until $x = 4/3$, and finally as soon as $x = 2$, the controller goes to state $\text{Win}$.  

![Fig. 7. A weighted timed game](image)

This example indicates that the region partitioning (of [3]) is not sufficient for solving optimal WTGs. Restricted decidability results have however been obtained in [1,7], but the general problem has been recently proved undecidable [10]. This result relies on a reduction which uses five clocks. A construction similar to that of $\text{WCTL}$ can be used to get a reduction with only three clocks, we sketch it now.

Given a two-counter machine $\mathcal{M}$ we construct a WTG $\mathcal{G}_M$ with one cost variable $\text{cost}$. The shape of the automaton is similar to the one described in Section 3, we only point out the few differences:

- When arriving in state $A_{\text{Halt}}$ we add a discrete cost 3;
- All arrows leading to a test module (dashed on the figures) are uncontrollable;
- The module for checking that $y = 2x$ is split into two branches, one setting the cost to $2 + 2x + (1 - y)$, and the other to $1 + 2(1 - x) + y$ (these two branches are slight adaptations of Fig. 5 and transitions leading to one or the other branch are uncontrollable). If the relation $y = 2x$ does not hold, the environment has a strategy to set the cost up to a value strictly greater than 3 (if $y < 2x$, he takes the branch storing $2 + 2x + (1 - y)$ in the cost, otherwise he takes the other branch). If the relation $y = 2x$ holds, then whatever branch chooses the environment, the accumulated cost will be exactly 3, and the controller will win the game;
- The module for checking that $y = 3x$ is similar, and has two branches, one setting the cost to $2 + 3x + (1 - y)$, and the other one setting the cost to $3(1 - x) + y$. Thus, if the relation $y = 3x$ does not hold, the environment has a strategy to set the
cost up to a value strictly greater than 3 (if \( y < 3x \), he takes the branch storing \( 2 + 3x + (1 - y) \) in the cost, otherwise he takes the other branch). If the relation \( y = 3x \) holds, then whatever branch chooses the environment, the accumulated will be exactly 3, and the controller will win the game;

- The modules \( \text{Power}_2 \) and \( \text{Power}_3 \) are similar to the one for WCTL (tests \( y = 2x \) (resp. \( y = 3x \)) are done as described above). In this module, if the controller cheats, that’s because at some point of the loop he does not satisfy \( y = 2x \) (resp. \( y = 3x \)), which can be detected by the environment going to the corresponding test module, or that’s because he will not be able to reach a location labelled by \( R_2 \) (or \( R_3 \)). In the first case, a state labelled by \( T \) will be reached (the play will thus be winning), but the cost will be strictly greater than 3, whereas in the second case, the play will not be winning.

Following the lines of [10] and our previous proof for WCTL: \( \mathcal{M} \) halts iff the controller has a winning strategy in \( \mathcal{G}_\mathcal{M} \) to enforce one of the states labelled by \{Halt, \( T, R_2, R_3 \}\) with cost less than or equal to 3. This is true because if the environment does not do any uncontrollable action, then the controller will have to never wait in states with a positive cost (otherwise the global cost will be strictly greater than 3). If the environment does an uncontrollable action, it means that he wants to check that the controller has played correctly, and if (and only if) the latter has really played correctly, he will be able to reach a state labelled by \( T, R_2 \) or \( R_3 \) with cost less than or equal to 3. Thus:

**Theorem 8** The problem of deciding whether there exists a winning strategy with cost less than or equal to a given value in a WTG with three clocks and one stopwatch cost is undecidable.

7 Conclusion

In this paper, we have improved two undecidability results of [9,10] by decreasing the number of clocks used in the reductions: both WCTL model-checking and optimal timed games are undecidable with three clocks and one stopwatch cost. These bounds are quite tight, as the same problems with only one clock are decidable. We did not manage to close the gap, with WTAs having two clocks, even when trying to encode both counter with only one clock \( x = 1/(2^c 3^{c2}) \). But on the other hand, for priced timed automata with two clocks and one stopwatch, the coarsest bisimulation has in general an infinite index [11].
