Undoped and Neodymium-doped gallium oxide (Ga_2O_3) thin films of about 500 nm thickness were successfully grown at different temperatures ranging from 100 up to 600 °C by radiofrequency magnetron sputtering. Post-annealing treatments were carried out at 900 °C and 1000 °C. The obtained films were (400) textured and a grain size of a few tens of

nanometres was found. Optical and electrical characterizations led to a figure of merit of about 1.9×10^{-4} . These films were successfully doped with Neodymium by a co-sputtering method. The photoluminescence experiments for the Nd-doped $\beta\text{-Ga}_2\text{O}_3$ films clearly showed the rare-earth emitting signature.

1 Introduction Recently, transparent conductive oxide (TCO) as alternative to expensive ITO have focused much attention owing to the wide variety of possible applications such as optical windows [1, 2], high temperature chemical gas sensor [3], and dielectric layer [4]. Gallium zinc oxide (GZO) thin films have shown high conductivity and transparent properties with figure of merit comparable to those of ITO materials [5]. Among promising TCO materials, Ga_2O_3 is a wide band gap semiconductor material (4.9 eV) and its conductivity can vary from insulator to conductor depending on the growth conditions [1, 2]. Over the past few years, by doping this material with rare-earth elements or 3d transition metal ions, Ga_2O_3 thin films have also shown promising optical and photoluminescent (PL) properties [6] as well as possible applications in electroluminescent devices (thin film electroluminescent displays) [7]. The most suitable structure for applications is the monoclinic $\beta\text{-Ga}_2\text{O}_3$ phase ($a = 1.221$ nm, $b = 0.304$ nm, $c = 0.580$ nm and $\beta = 103.8^\circ$, space group: $C2/m$) which appears to be extremely stable chemically and thermally (melting point at 1800 °C) and may be an alternative choice to other transparent conductive oxide (TCO) materials (sulphide-based phosphors) usually dedicated to optoelectronic devices. Various growth techniques have been

used to prepare thin films of this material: electron beam evaporation [8], spray pyrolysis deposition [9], sol gel process [7] and radiofrequency (RF) magnetron sputtering [10].

In the present paper, we report the use of RF magnetron sputtering to prepare undoped $\beta\text{-Ga}_2\text{O}_3$ thin films. Structural characterizations, optical absorption as well as electrical conductivity properties are studied versus anneal treatments during and after the growth process. In addition, Nd-doped $\beta\text{-Ga}_2\text{O}_3$ thin films have been fabricated by co-sputtering and the first PL data show the emitting signatures of the rare earth element in the infrared spectral region.

2 Experimental details Gallium oxide Ga_2O_3 thin films were prepared by radio-frequency magnetron sputtering of a Ga_2O_3 (99.99% purity) target. Before any deposit, the chamber was evacuated down to 1.0×10^{-7} Torr. The substrate temperature (T_s) during deposit was varied over the range 100–600 °C. Then the layers were grown on single crystal silicon substrates under a pure argon pressure of 2.5×10^{-2} Torr and a power density of 2.5 W/cm². The thickness of the deposited films ranged between 250 nm and 600 nm. For each T_s value, (100)-oriented silicon sub-

strates were placed in the chamber, side by side and at 7 cm just above the target. Post-annealing treatments were carried out at $T_a = 900^\circ\text{C}$ and 1000°C during 1 hour under a continuous flow of pure nitrogen. Nd-doping was achieved by placing a few pellets of Neodymium oxide on the target surface during the growth process corresponding to a surface ratio of about 5%.

Various characterization techniques were used to analyse the evolution of the structural, optical and electrical properties of the films upon growth conditions (T_s) and post-anneal treatments (T_a). X-ray spectroscopy measurements were performed using a Philips XPERT diffractometer with Cu K_α ($\lambda = 1.5418 \text{ \AA}$) as X-ray source. Usual θ - 2θ diagrams were recorded under a grazing incidence of 0.5° . Conventional and high resolution Transmission Electron Microscopy (TEM) observations of cross sectional views of the films were performed using a JEOL 2010F operated with a Field Emission Gun source at 200 kV, and equipped with a CCD camera. The ellipsometric spectroscopy (ES) data were collected while the incident light was scanned between 1.5 eV and 5.0 eV under an incidence angle of 66.2° . This was realized by means of a Jobin–Yvon ellipsometer (UVISEL). The ES spectra consist in the measurement of ψ and Δ ellipsometric angles defined from the fundamental equation of ellipsometry:

$$r_p/r_s = \tan \psi e^{i\Delta}, \quad (1)$$

where r_p and r_s are the complex reflection coefficients for parallel and perpendicular polarizations of the light, respectively. The sheet resistance is a measure of resistance of thin films that have a uniform thickness. It is applicable to two-dimensional systems where the thin film is considered to be a two dimensional entity and is equivalent to resistivity as used in three-dimensional systems. In a regular three-dimensional conductor, the resistance can be written as:

$$R = \rho \frac{L}{eW}, \quad (2)$$

where ρ is the resistivity, L is the length, W is the width and e the sheet thickness. By grouping the resistivity with the thickness, the resistance can then be written as:

$$R = R_s \frac{L}{W} \quad \text{with} \quad R_s = \frac{\rho}{e}. \quad (3)$$

R_s is then the sheet resistance in ohms/square ($\Omega/\square$). For a square, $L = W$ and therefore, $R = R_s$. PL response was investigated at room temperature using an Ar laser line which induces a resonant excitation of Nd (operating at 514 nm). The emission was recorded through a system of measurement composed by a chopper, a monochromator (Jobin–Yvon THR1000) followed by a cooled Ge detector and a lock-in amplifier. The PL measurement was carried out with a laser beam chopped at 45 Hz and an excitation power of 1.3 W/cm^2 .

3 Results and discussion

3.1 Substrate temperature effect All the synthesised films were found to be amorphous whatever the chosen T_s value. The XRD patterns obtained for all the T_s values (not shown) give rise to similar spectra: two broad bands centred at about 32° and 64° are visible. These positions correspond approximately to the positions of the main diffraction peaks of $\beta\text{-Ga}_2\text{O}_3$. These broad bands could suggest the presence of a nanocrystalline structure of the films but TEM observations (not shown) showed that they were fully amorphous. The films were also subject to SE analyses by using a model dealing with an appropriate dispersion law such as Forouhi–Bloomer [11] and the Bruggeman effective medium approximation (EMA) [12]. Such analyses were already described elsewhere in the case of silicon nanoparticles embedded in a silica matrix [13].

The deduction of the optical parameters from the ellipsometric angles ψ and Δ requires the reproduction of the experimental values in the energy range 1.5–5 eV. Although the EMA approach could appear more realistic for our material that might be considered as containing components of both crystalline and amorphous Ga_2O_3 , it requires, however, the existence of reference spectra for these media. As example, we chose as a reference for silicon substrate, data contained in the software DELTAPSI2 from Jobin–Yvon. Concerning the Ga_2O_3 films, the dispersion law which models the dielectric function, called “new amorphous” has been used. It derives from the Forouhi–Bloomer law, commonly used in the case of both semiconducting and insulating materials. A nearly perfect agreement between the measured and calculated spectra was obtained and the thickness agrees well with that obtained by other techniques. However, the major data extracted from the modelling are the optical properties as will be discussed hereafter. Figure 1 depicts the static (in the infrared region) refractive index spectra n and the deposition rate as

Figure 1 Static refractive index (n) and deposition rate versus substrate temperature. n is constant with a value (about 1.91) close to that of bulk Ga_2O_3 and the deposition rate is decreasing when T_s is raised.

Figure 2 X-ray diffraction patterns of annealed gallium oxide films. Diffraction peaks positions are consistent with the monoclinic β -Ga₂O₃ structure. The high intensity of the (400) peak suggests a (400) texture of the film.

a function of the substrate temperature T_s . Upon increasing T_s , n is almost constant (close to the value of bulk Ga₂O₃, $n = 1.91$) whereas the deposition rate decreases in a monotonous way. This behaviour is usual and is explained by a larger reactivity of the species produced within the plasma when T_s increases [14].

3.2 Annealing temperature effect Anneal treatments were performed on films grown at $T_s = 100$ °C. Figure 2 shows the XRD spectra of gallium oxide thin films annealed at 900 °C and 1000 °C under a continuous flow of pure nitrogen. Diffraction peaks appear for both samples and their positions are consistent with the monoclinic structure of Ga₂O₃ (β -Ga₂O₃). However, higher intensities are observed for the sample annealed at 1000 °C indicating a better formation of the β -Ga₂O₃ phase.

Compared to a diffraction spectrum of a powder β -Ga₂O₃ specimen, the intense (111) diffraction peak is missing and the highest intensity is observed for the peak related to the (400) planes suggesting thus a (400) preferred orientation of the films. There is no observable secondary phase in the XRD patterns. TEM observations led to an estimate of the grain size of a few tens of nanometres. Figure 3(a) is a typical HREM image of a film annealed at 1000 °C. This region shows a grain oriented such that the Fourier transform in Fig. 3(b) is in accordance with the monoclinic structure of Ga₂O₃. The grain orientation is also consistent with the above mentioned (400) texture of the films.

Figure 3 (a) HREM image of an annealed film at 1000 °C, (b) Fourier transform of the image in Fig. 3(a). These data confirm the formation of β -Ga₂O₃ and the (400) texture of the films.

The T_a effect on the absorption coefficient α is shown in Fig. 4 which compares the $\alpha(E)$ spectra obtained from ellipsometry measurements for as-grown and annealed samples. These data reveal that all the samples are almost transparent below 3 eV whereas a clear improvement appears when T_a increases.

However, close to 5 eV, the T_a effect is weak. This behaviour shows that the thin films become more transparent after post-annealing than for the as-grown sample. Annealing treatment allows certainly a crystallization of the films whose composition becomes close to that of the target. This seems to be confirmed by the electrical measurements. Indeed, Table 1 gives the values of the sheet resistances obtained for as-grown and annealed samples. One observes a decrease in resistance with T_a and thus indicates an improvement of the film conductivity. In Table 1 are also reported the absorption coefficient values at $E = 2.3$ eV (corresponding to the medium of the visible range) and the transmission coefficients of the films calculated by $T = e^{-\alpha x}$. It is then possible to calculate the figure of merit Φ_{TC} of the transparent conductive sample by the following equation:

$$\Phi_{TC} = \frac{T^{10}}{R_s} \quad (4)$$

The obtained values show that they are very satisfactory compared to those of other operating TCOs (about 1.0×10^{-3} for ZnO [15], and 2.0×10^{-3} for ZGO [16] and we can observe an increase of this factor with the annealing temperature.

Regarding the Nd-doped β -Ga₂O₃ films, optical properties are very close to those of non doped films. By EDX analysis, the Nd concentration does not exceed 1% corresponding to the detection limit of the spectrometer. Fig-

Table 1 Electrical and optical data of the gallium oxide films.

sample	L (mm)	e (nm)	W (mm)	R (Ω)	R_s ($\Omega/\square$)	α (cm ⁻¹)	T	Φ (Ω^{-1})
as-grown	10	544	5	3947	7895	431.0	0.98	1.0×10^{-4}
900 °C	10	590	5	3409	6818	7.4	1.00	1.5×10^{-4}
1000 °C	6	590	5	2113	2535	1370	0.93	1.9×10^{-4}

ure 5 exhibits the PL response of the Nd-doped β -Ga₂O₃ film annealed at 1000 °C.

The rare-earth signature is clearly visible at 880 nm and 1070 nm corresponding respectively to 4F transitions respectively $4F_{3/2} \rightarrow 4I_{11/2}$ and $4F_{3/2} \rightarrow 4I_{9/2}$ of Nd³⁺. This first result is encouraging and optimisation of the process is in progress. For instance, the effect of the number of pellets on the target as well as the anneal treatment has to be investigated and optimised. Very recently, a similar approach using a subdivided powder target into two or more parts led to multicomponent thin film phosphors for electroluminescent devices [17]. Our goal is to obtain similar results with our method.

Figure 5 PL spectrum for the Nd-doped β -Ga₂O₃ film annealed at 1000 °C. Nd signature is clearly identified by the presence of two peaks of luminescence at 880 nm (a) and 1070 nm (b).

4 Conclusion β -Ga₂O₃ polycrystalline thin films have been successfully grown by RF magnetron sputtering. The β -Ga₂O₃ phase appears upon an anneal treatment at about 900 °C. The grain size is a few tens of nanometres and the films are (400) textured. A T_a increase favours a better figure of merit up to 1.9×10^{-4} for $T_a = 1000$ °C. A possible application of this material is transparent electrodes under extreme thermal conditions. Nd-doped films have been achieved with success since the typical emitting signals from Nd in the infrared region have been easily detected. This co-sputtering method of doping β -Ga₂O₃ films is then promising and will be optimised to fabricate light emitting diodes. These studies will be extended to other rare-earth elements.
