HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Unilateral contact induced blade/casing vibratory interactions in impellers: analysis for flexible casings with friction and abradable coating

Alain Batailly*, Mathias Legrand

Abstract

This contribution addresses the vibratory analysis of unilateral contact induced structural interactions between a bladed impeller and its surrounding flexible casing. It extends the numerical developments exposed in a previous article to flexible casings. The casing finite element model and the construction of the associated reduced-order model for efficient computations are first exposed in details along with an extensive presentation of the smoothing strategy implemented on the contact interface. The proposed algorithms embedding unilateral contact conditions together with abradable coating removal are subsequently introduced and validated through a systematic analysis of (1) the nonlinear procedure for the computation of impeller/casing distances, (2) the treatment of three-dimensional friction and contact forces, (3) the correction of the displacements when unilateral contact or abradable removal arises, and (4) the possible hybrid contact scenarios involving localized total removal of the abradable coating. Finally, two illustrative case studies show that the linear interaction condition, commonly considered for the safe design of impellers and casings in turbomachinery, may be advantageously combined with the presented numerical strategy in order to assess the actual importance of predicted critical speeds.

Interactions générées par les contacts aubes/carter pour un rouet centrifuge: étude avec carters flexibles, frottement et revêtement abradable

Alain Batailly*, Mathias Legrand

Résumé

Cet article porte sur l'analyse vibratoire de phénomènes d'interaction initiés par des contacts structurels entre un rouet centrifuge et le carter flexible environnant. Il étend ainsi les développements numériques présentés dans un article précédent au cas de carters flexibles. Le modèle éléments finis du carter, le modèle réduit associé et l'outil mathématique utilisé pour lisser sa surface de contact sont tout d'abord présentés en détails. L'algorithme de résolution permettant de traiter des conditions de contact unilatéral avec l'enlèvement du matériau abradable est ensuite décrit et validé en se focalisant sur: (1) la procédure non-linéaire utilisée pour le calcul des distances aube/carter, (2) la prise en compte des efforts de contact en trois dimensions, (3) la correction des déplacements lorsque des contacts avec le carter ou le revêtement abradable sont prédits, et (4) de possibles scénarios de contact hybrides avec un enlèvement total mais localisé du revêtement abradable. Enfin, deux études de cas mettent en évidence que les critères linéaires de prédiction des interactions, usuellement utilisés pour la conception des turbomachines, gagnent à être enrichis de la stratégie numérique proposée dans le but d'estimer la criticité d'un point d'interaction prédit.

Nomenclature

α_p	internal hardening variable
Γ	a boundary node along a blade tip of the impeller
λ	contact forces vector
$\Delta\varepsilon_p$	plastic deformation of an abradable element

η	number of abradable elements along the casing circumference
$\mathbf{D}$	damping matrix
$\mathbf{d}$	distance vector
$\mathbf{K}$	stiffness matrix
$\mathbf{MC}$	contact matrix of the time-stepping procedure
$\mathbf{M}$	mass matrix
$\mathbf{n}_{\text{out}}$	outward normal vector to the contact surface
$\mathbf{P}$	data points of the spline surface: boundary nodes of the casing model
$\mathbf{Q}$	control points of the spline surface
$\mathbf{Q}_{\text{bo}}$	control points on the edges of the spline surface
$\mathbf{Q}_{\text{int}}$	control points inside the spline surface
$\mathbf{t}$	tangential vector to the contact surface
$\mathbf{VCT}$	contact constraints matrix in radial and tangential directions
$\mathbf{VC}$	contact constraints matrix in the radial direction
$\mathbf{v}$	displacement field
$\mathcal{E}$	strain energy
$\mathcal{Q}^{i,j}$	control points related to the patch $\mathcal{S}^{i,j}$
$\mathcal{S}^{i,j}$	a patch of the spline surface
μ	friction coefficient
ϕ	free vibration mode of the impeller
ε_{NR}	Newton-Raphson iterative procedure stop criterion
*	superscript relative to predicted quantities
c	subscript relative to the casing
i	subscript relative to the impeller
e_{abr}	abradable coating thickness
h	time step of the time integration scheme
M	number of boundary nodes per casing sector
N	number of casing sectors
u	first intrinsic coordinate of a point over the spline surface
v	second intrinsic coordinate of a point over the spline surface

1. Introduction

In a previous article [1], a numerical strategy for the analysis of unilateral contact induced blade/casing vibratory interactions in industrial impellers was derived assuming that the surrounding casing is perfectly rigid. This assumption is frequently considered in the modeling of blade-tip/casing rubbing phenomena. Existing publications on experimental rigs involving axial compressors commonly underscore that the dynamics of the casing is often negligible [2]. However, this is in contradiction with a recent study [3] which suggests that significant displacements may be observed in such systems, possibly induced by a critical vibratory coupling known as *modal coincidence* [4]. In this context, modeling flexible casings in aeronautical engines is crucial and this article extends the numerical strategy presented in [1].

The structural flexibility of the casing significantly increases the numerical complexity of the contact treatment and a thorough analysis must be undertaken in order to validate the presented results. In that sense, this paper is complementary to [1]: all the qualitative developments regarding the aliasing effect, the harmonic tracking procedure or the two-dimensional Fourier transform explained in [1] are still relevant and this work extends their scope to the general framework of unilateral contact occurrences between two *flexible* structures. A fully nonlinear contact detection procedure is incorporated in the solution method in order to handle any contact interface, irrespective of its geometrical curvature and shape. In addition, this article extends the numerical developments of [1] to 3D friction forces using a Coulomb law assuming only sliding occur. The removal of the sacrificial abradable coating deposited on the casing inner surface in order to avoid contact-induced damages is also accounted for. Accordingly, the proposed developments shall be adapted with no supplementary effort to a variety of systems such as automotive turbochargers, micro-rotors, or gas turbines, and are suitable to configurations ranging from the rubbing of a single blade to modal interaction coupling the dynamics of a full bladed disk and the surrounding casing.

Recent publications dealing with abradable coatings show the need for an improved understanding of the structural behaviour of such materials during impact. Among the open questions is the mechanism of material transfers between the impacting structure and

the abradable coating during rubbing events [5, 6], which is one of the motivations for blade repair technological enhancements [7]. Experimenters mostly explore the static and dynamic characterizations of the abradable coating mechanical behaviour while numericists are investigating workable ways to model it. From an experimental standpoint, several studies may be found on the static characterization of abradable coatings [8, 9, 10]. Similarly, several abradability investigations carried out statically—or at very low speed—are available [11, 12] in addition to a few scratch tests [13, 14].

In the context of turbomachinery, one should mention the pioneering work [15] on wear mechanisms in gas turbines. Recently, experimental investigations on the dynamic characterization of abradable coatings within a simulated turbomachine environment were reported with respect to: a high relative interaction speed [16, 17, 18], elevated temperatures [19] as well as a combination of high interaction speed and elevated temperatures [20, 21]. While the influence of thermal conditions has long been investigated [22], experimental work carried out by industrials is rarely published. The only study which suggests a numerical model of the abradable coating is [9]: it aims at reproducing HR15Y test results. Based on the finite element method, a micro model is also proposed in [23] in order to correlate observations made in the micro-structure to the mechanical properties of the macro-structure. However, in the context of an expensive time marching strategy, such as the one employed in the present article, this model is not appropriate. To the authors' knowledge, only two models are available in the literature for the modeling of abradable coating in the context of full 3D simulations [24, 25]. The model proposed in [24] is used in this paper. It relies on mono-dimensional plastic finite elements—called abradable elements in the following.

The second section of the article centers on the modeling of the casing, and attention is paid to the mathematical smoothing of its contact interface: the corresponding formulation and its integration within the time marching algorithm are extensively detailed. The third section describes the contact algorithm and its validation. The nonlinear procedure dedicated to the computation of blades/casing distances is outlined as the central ingredient of the proposed time-marching strategy and attention is also paid to the contact constraints matrices. The fourth section introduces the modeling and associated numerical implementation of the abradable coating removal process. The possibility of simulating sophisticated interactions featuring a localized yet full removal of the abradable coating is discussed. Finally, the last two sections introduce illustrative case studies of the problem of interest. The first case study explores the response sensitivity to the friction coefficient and the abradable coating mechanical properties and the second case study targets a structural vibration analysis in the vicinity of a critical angular speed.

Note Amplitudes are normalized with respect to reference data for confidentiality purposes.

2. Contact treatment between two flexible structures

The model of the impeller extensively described in [1] is used in this work and thus not recalled. Instead the focus is on the casing, the mathematical smoothing of its contact interface and the nonlinear contact treatment procedure devoted to the accurate detection of penetrations between the structures.

2.1 Casing modeling

The casing, assumed perfectly tuned, exhibits axial symmetry and is meshed with usual families of 3D finite elements. In this context, the advantageous mathematical properties brought by the theory of cyclic symmetry are considered for the efficient computation of its reduced-order model: accordingly, it is first divided in $N = 100$ identical sectors as pictured in Fig. 1. The boundary conditions are prescribed in agreement with typical assembly conditions within an aeronautical engine: nodes belonging to the red hatched area in Fig. 1 are clamped. A few corresponding free vibration modes are depicted in Fig. 2. Also, a quadratic brick mesh of one reference

Figure 1. Surrounding casing of the impeller used in [1]

sector is presented in Fig. 3. This mesh contains 4,685 nodes and 784 elements so that the full 360-degree structure has 374,800 nodes and 78,400 elements. As illustrated in Fig. 3, the $M = 5$ boundary nodes of the sector define the contact interface of this sector. In other words, $N \times M$ nodes are used for the definition of the full casing contact interface. This finite element model is reduced in the exact same fashion as the impeller in [1]: this combines cyclic symmetry to the Craig-Bampton component mode synthesis method [26]. The only difference between the reduction procedure of the casing and the impeller lies in the fact that centrifugal stiffening is omitted for the casing.

Figure 2. Free vibration modes of the casing: (a) one nodal diameter, (b) two nodal diameters, (c) three nodal diameters, (d) four nodal diameters. The reader may refer to [1] for more details regarding the notion of *nodal diameters*.

2.2 Contact surface functional smoothing

As evidenced in Fig. 3, all together the boundary nodes of each sector draw the supporting frame of the casing contact surface. It is explained in previous works [27, 28] that there is a need for contact surfaces smoothing when dealing with nonlinear contact simulations with industrial finite element models. Such models are typically made of quadratic finite elements that feature a discontinuity of the normal to the outer surface when sliding from an element to another. This discontinuity may trigger numerical instabilities—commonly known as the chatter effect—with 3D node-to-surface contact algorithms [29, 30]. Solutions exist to bypass such discontinuity through a modification of the finite element type, with Hermite-like elements [31, 28] for instance. They are promising yet not fully satisfying from an industrial standpoint as they usually lead to an increased computational cost. Competitive techniques involve contact surface smoothing through a mathematical artefact, be it a B-spline [30], a non-uniform rational B-spline (NURBS) or Nagata patches [32], as an additional virtual layer on top of the finite element contact surface. This mathematical layer is solely dedicated to the computation of gap functions and the direction of contact forces. In the present work, a bicubic B-spline is used. The formulation of these splines can be efficiently combined with the considered contact algorithm. Additionally, they are particularly well suited to the reduced-order models and ensure a perfect symmetry of the casing inner contact surface at rest. The numerical developments detailed in the remainder form an extension of a previous work [27]. The two-dimensional spline is here intended to reflect any contact interface geometry irrespective of its curvature in the axial direction for instance. Contrary to [27], more elaborate impeller casings may be accommodated and a fully nonlinear contact detection procedure is implemented. The improvements with respect to the developments presented in [27] are detailed in Tab. 1.

2.2.1 Bicubic B-spline and associated notations

A bicubic B-spline is typically defined by a set of control points, denoted $\mathbf{Q} = \mathbf{Q}(i, j)$ with $i = 1, \dots, N + 3$ and $j = 1, \dots, M + 2$ in this paper. One may compute the location of the data points, denoted $\mathbf{P} = \mathbf{P}(i, j)$ with $i = 1, \dots, N + 1$ and $j = 1, \dots, M$ which actually define the surface, based on:

$$\mathbf{P}^* = \mathbf{A}\mathbf{Q}^* \quad (1)$$

Figure 3. Partial representation of the spline attached to the casing contact surface. Boundary nodes of the first sector are denoted $P(1,i)$, $i = 1, \dots, M$ (corresponding control points Q are not plotted)

Table 1. Differences between present numerical developments and reference [27]

	present work	reference [27]
blade/casing distances computation	iterative nonlinear procedure	simplified procedure
hypotheses on the casing displacement	none	radial only
friction	full 3D	tangential direction

where $\mathbf{A}$ is a rectangular matrix referred to as the *interpolation matrix*. It should be noted that $\mathbf{Q}(i, j) \in \mathbb{R}^3$ and $\mathbf{P}(i, j) \in \mathbb{R}^3$. The data points are the boundary nodes, pictured in Fig. 3, of the finite element model of the casing. The $\blacktriangledown$ superscript indicates that points are arranged in a single column vector following the convention:

$$\mathbf{X}^\blacktriangledown = \begin{bmatrix} \mathbf{X}(1, 1) \\ \mathbf{X}(1, 2) \\ \mathbf{X}(1, 3) \\ \vdots \\ \mathbf{X}(i, j) \\ \vdots \\ \mathbf{X}(n, m-2) \\ \mathbf{X}(n, m-1) \\ \mathbf{X}(n, m) \end{bmatrix}, \text{ with: } \mathbf{X} = \mathbf{X}(i, j), \quad i = 1, \dots, n, \quad j = 1, \dots, m \quad (2)$$

The control points may be divided into two complementary sets: namely the interior points $\mathbf{Q}_{\text{int}} = \mathbf{Q}(i, j)$ for $i = 2, \dots, N+2$ and $j = 2, \dots, M+1$ and the boundary points $\mathbf{Q}_{\text{bo}} = \mathbf{Q}(i, j)$ for $i = 1, N+3$ and $j = 1, M+2$, and by construction:

$$\begin{aligned} \mathbf{Q}_{\text{bo}} \cap \mathbf{Q}_{\text{int}} &= \{\emptyset\} \\ \mathbf{Q}_{\text{bo}} \cup \mathbf{Q}_{\text{int}} &= \mathbf{Q} \end{aligned} \quad (3)$$

From the definition of the boundary conditions, the following relation can be established:

$$\mathbf{Q}^\blacktriangledown = \mathbf{C} \mathbf{Q}_{\text{int}}^\blacktriangledown \quad (4)$$

Note that the number of interior points $\mathbf{Q}_{\text{int}}$ is equal to the number of data points $\mathbf{P}$ so that matrices $\mathbf{A}$ and $\mathbf{C}$ have the same size. Equations (1) and (4) shall thus be combined as follows:

$$\mathbf{Q}^\blacktriangledown = \mathbf{C} [\mathbf{A} \mathbf{C}]^{-1} \mathbf{P}^\blacktriangledown = \mathbf{B} \mathbf{P}^\blacktriangledown \quad (5)$$

Equation (5) reverses the usual definition of a bicubic B-spline given in Eq. (1) as control points $\mathbf{Q}$ are obtained from a set of known data points $\mathbf{P}$, that is the casing boundary nodes. In this article, the computation of the control points $\mathbf{Q}$ based on Eq. (5) is referred to as *the computation of the spline surface*. Accordingly, at each time-step of the solution algorithm, the spline is supported by the predicted coordinates of the casing boundary nodes.

2.2.2 Computation of the interpolation matrix $\mathbf{A}$

Equation (6) defines a single patch $\mathcal{S}^{i,j}(u, v)$ depicted in Fig. 3. Notations u and v refer to the intrinsic coordinates of any point belonging to the spline. For a bicubic B-spline, it may be shown that for $u, v \in [0; 1]$:

$$\mathcal{S}^{i,j}(u, v) = \frac{1}{36} \begin{bmatrix} v^3 & v^2 & v & 1 \end{bmatrix} \begin{bmatrix} -1 & 3 & -3 & 1 \\ 3 & -6 & 3 & 0 \\ -3 & 0 & 3 & 0 \\ 1 & 4 & 1 & 0 \end{bmatrix} \mathcal{Q}^{i,j} \begin{bmatrix} -1 & 3 & -3 & 1 \\ 3 & -6 & 0 & 4 \\ -3 & 3 & 3 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} u^3 \\ u^2 \\ u \\ 1 \end{bmatrix} \quad (6)$$

where:

$$\mathcal{Q}^{i,j} = \begin{bmatrix} \mathbf{Q}(i, j) & \mathbf{Q}(i, j+1) & \mathbf{Q}(i, j+2) & \mathbf{Q}(i, j+3) \\ \mathbf{Q}(i+1, j) & \mathbf{Q}(i+1, j+1) & \mathbf{Q}(i+1, j+2) & \mathbf{Q}(i+1, j+3) \\ \mathbf{Q}(i+2, j) & \mathbf{Q}(i+2, j+1) & \mathbf{Q}(i+2, j+2) & \mathbf{Q}(i+2, j+3) \\ \mathbf{Q}(i+3, j) & \mathbf{Q}(i+3, j+1) & \mathbf{Q}(i+3, j+2) & \mathbf{Q}(i+3, j+3) \end{bmatrix} \quad (7)$$

with $i = 1, \dots, N$ and $j = 1, \dots, M - 1$. Data points are located at each corner of a patch for $(u, v) = (0, 0)$, $(u, v) = (0, 1)$, $(u, v) = (1, 1)$, and $(u, v) = (1, 0)$ which yields the coordinates of the data points:

$$\begin{aligned}
\mathbf{P}(i, j) &= \mathcal{S}^{i,j}(0, 0) \\
&= \frac{1}{36} [\mathbf{Q}(i, j) + 4\mathbf{Q}(i, j+1) + \mathbf{Q}(i, j+2) + 4\mathbf{Q}(i, j+3) \\
&\quad + 16\mathbf{Q}(i+1, j+1) + 4\mathbf{Q}(i+1, j+2) + \mathbf{Q}(i+2, j) + 4\mathbf{Q}(i+2, j+1) \\
&\quad + \mathbf{Q}(i+2, j+2)] \\
\mathbf{P}(i, j+1) &= \mathcal{S}^{i,j}(0, 1) \\
&= \frac{1}{36} [\mathbf{Q}(i+1, j) + 4\mathbf{Q}(i+1, j+1) + \mathbf{Q}(i+1, j+2) + 4\mathbf{Q}(i+2, j) \\
&\quad + 16\mathbf{Q}(i+2, j+1) + 4\mathbf{Q}(i+2, j+2) + \mathbf{Q}(i+3, j) + 4\mathbf{Q}(i+3, j+1) \\
&\quad + \mathbf{Q}(i+3, j+2)] \\
\mathbf{P}(i+1, j) &= \mathcal{S}^{i,j}(1, 0) \\
&= \frac{1}{36} [\mathbf{Q}(i, j+1) + 4\mathbf{Q}(i, j+2) + \mathbf{Q}(i, j+3) + 4\mathbf{Q}(i+1, j+1) \\
&\quad + 16\mathbf{Q}(i+1, j+2) + 4\mathbf{Q}(i+1, j+3) + \mathbf{Q}(i+2, j+1) \\
&\quad + 4\mathbf{Q}(i+2, j+2) + \mathbf{Q}(i+2, j+3)] \\
\mathbf{P}(i+1, j+1) &= \mathcal{S}^{i,j}(1, 1) \\
&= \frac{1}{36} [\mathbf{Q}(i+1, j+1) + 4\mathbf{Q}(i+1, j+2) + \mathbf{Q}(i+1, j+3) \\
&\quad + 4\mathbf{Q}(i+2, j+1) + 16\mathbf{Q}(i+2, j+2) + 4\mathbf{Q}(i+2, j+3) \\
&\quad + \mathbf{Q}(i+3, j+1) + 4\mathbf{Q}(i+3, j+2) + \mathbf{Q}(i+3, j+3)]
\end{aligned} \tag{8}$$

From these four equations arises the pattern of the general linear relationship between the data and control points in Eq. (1) with:

$$\mathbf{A} = \begin{bmatrix} 1 & 4 & 1 & 0 & \dots & 4 & 16 & 4 & 0 & \dots & 1 & 4 & 1 & 0 & \dots & 0 & 0 \\ 0 & 1 & 4 & 1 & 0 & \dots & 4 & 16 & 4 & 0 & \dots & 1 & 4 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & 4 & 1 & 0 & \dots & 4 & 16 & 4 & 0 & \dots & 1 & 4 & 1 & 0 & \dots \\ \vdots & & & & & & & & & \ddots & & & & & & \vdots \\ 0 & \dots & 1 & 4 & 1 & 0 & \dots & 4 & 16 & 4 & 0 & \dots & 1 & 4 & 1 & 0 & \dots \\ 0 & \dots & 0 & 1 & 4 & 1 & 0 & \dots & 4 & 16 & 4 & 0 & \dots & 1 & 4 & 1 & 0 \\ 0 & \dots & 0 & 0 & 1 & 4 & 1 & 0 & \dots & 4 & 16 & 4 & 0 & \dots & 1 & 4 & 1 \end{bmatrix} \tag{9}$$

The matrix $\mathbf{A}$ is independent of the coordinates of the data points $\mathbf{P}$ and does not have to be updated during computation.

2.2.3 Spline boundary conditions: computation of matrix $\mathbf{C}$

As mentioned above, matrix $\mathbf{C}$ is related to the boundary conditions imposed on the spline surface. Based on the notations introduced in Fig. 3, four edges to the spline surface are considered:

- $v = 0$ and $v = M$: these two edges—which refer respectively to the control points $\mathbf{Q}(i, 1)$ with $i = 2, \dots, N$ and $\mathbf{Q}(i, M+2)$ with $i = 2, \dots, N$ —are defined as free edges:

$$\begin{aligned}
\mathbf{Q}(i, 1) &= 2\mathbf{Q}(i, 2) - \mathbf{Q}(i, 3), \quad i = 2, \dots, N \\
\mathbf{Q}(i, M+2) &= 2\mathbf{Q}(i, M+1) - \mathbf{Q}(i, M), \quad i = 2, \dots, N
\end{aligned} \tag{10}$$

- $u = 0$ and $u = N$: this is where the spline surface is closed and refers to the control points $\mathbf{Q}(1, j)$ with $j = 1, \dots, M+2$ and $\mathbf{Q}(N+3, j)$ with $j = 1, \dots, M+2$. Along the closing line, it is ensured that first and second derivatives of the position with respect to u are equal one to another:

$$\begin{aligned}
\frac{\partial \mathcal{S}^{i=1,j}}{\partial u}(u=0, v) &= \frac{\partial \mathcal{S}^{i=N,j}}{\partial u}(u=1, v), \quad j = 1, \dots, M-1 \\
\frac{\partial^2 \mathcal{S}^{i=1,j}}{\partial u^2}(u=0, v) &= \frac{\partial^2 \mathcal{S}^{i=N,j}}{\partial u^2}(u=1, v), \quad j = 1, \dots, M-1
\end{aligned} \tag{11}$$

These conditions lead to the following $2(M+2)$ equations:

$$\begin{aligned}
\mathbf{Q}(1,1) &= 2\mathbf{Q}(2,2) - \mathbf{Q}(2,3) + 2\mathbf{Q}(N+1,2) - \mathbf{Q}(N+1,3) \dots \\
&\dots - 2\mathbf{Q}(N+2,2) + \mathbf{Q}(N+2,3) \\
\mathbf{Q}(1,2) &= \mathbf{Q}(2,2) + \mathbf{Q}(N+1,2) - \mathbf{Q}(N+2,2) \\
\mathbf{Q}(1,3) &= \mathbf{Q}(2,3) + \mathbf{Q}(N+1,3) - \mathbf{Q}(N+2,3) \\
&\vdots \\
\mathbf{Q}(1,M) &= \mathbf{Q}(2,M) + \mathbf{Q}(N+1,M) - \mathbf{Q}(N+2,M) \\
\mathbf{Q}(1,M+1) &= \mathbf{Q}(2,M+1) + \mathbf{Q}(N+1,M+1) - \mathbf{Q}(N+2,M+1) \\
\mathbf{Q}(1,M+2) &= -\mathbf{Q}(2,M) + 2\mathbf{Q}(2,M+1) - \mathbf{Q}(N+1,M) \dots \\
&\dots + 2\mathbf{Q}(N+1,M+1) + \mathbf{Q}(N+1,M) - 2\mathbf{Q}(N+2,M+2) \\
\mathbf{Q}(N+3,1) &= -2\mathbf{Q}(2,2) + \mathbf{Q}(2,3) + 2\mathbf{Q}(3,3) - \mathbf{Q}(3,3) + 2\mathbf{Q}(N+2,2) - \mathbf{Q}(N+2,3) \\
\mathbf{Q}(N+3,2) &= -\mathbf{Q}(2,2) + \mathbf{Q}(3,2) + \mathbf{Q}(N+2,2) \\
\mathbf{Q}(N+3,3) &= -\mathbf{Q}(2,3) + \mathbf{Q}(3,3) + \mathbf{Q}(N+2,3) \\
&\vdots \\
\mathbf{Q}(N+3,M) &= -\mathbf{Q}(2,M) + \mathbf{Q}(3,M) + \mathbf{Q}(N+2,M) \\
\mathbf{Q}(N+3,M+1) &= -\mathbf{Q}(2,M+1) + \mathbf{Q}(3,M+1) + \mathbf{Q}(N+2,M+1) \\
\mathbf{Q}(N+3,M+2) &= \mathbf{Q}(2,M) - 2\mathbf{Q}(2,M+1) - \mathbf{Q}(3,M) \dots \\
&\dots + 2\mathbf{Q}(3,M+1) - \mathbf{Q}(N+2,M) + 2\mathbf{Q}(N+2,M+1)
\end{aligned} \tag{12}$$

All these equations sum up to Eq. (4) with:

$$\mathbf{C} = \begin{bmatrix} 2 & -1 & 0 & \dots & 0 & 2 & -1 & 0 & \dots & 0 & -2 & 1 & 0 & \dots & 0 \\ 1 & 0 & 0 & \dots & 0 & 1 & 0 & 0 & \dots & 0 & -1 & 0 & 0 & \dots & 0 \\ 0 & 1 & 0 & \dots & 0 & 0 & 1 & 0 & \dots & 0 & 0 & -1 & 0 & \dots & 0 \\ \vdots & & & & & & & \ddots & & & & & & & \vdots \\ 0 & \dots & 0 & 1 & 0 & 0 & \dots & 0 & 1 & 0 & 0 & \dots & 0 & -1 & 0 \\ 0 & \dots & 0 & 0 & 1 & 0 & \dots & 0 & 0 & 1 & 0 & \dots & 0 & 0 & -1 \\ 0 & \dots & 0 & -1 & 2 & 0 & \dots & 0 & -1 & 2 & 0 & \dots & 0 & 1 & -2 \\ 2 & -1 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \vdots & & & & & & & \ddots & & & & & & & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & -1 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & -1 & 2 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & 0 & 0 & -1 & 2 \\ -2 & 1 & 0 & \dots & 0 & 2 & -1 & 0 & \dots & 0 & 2 & -1 & 0 & \dots & 0 \\ -1 & 0 & 0 & \dots & 0 & 1 & 0 & 0 & \dots & 0 & 1 & 0 & 0 & \dots & 0 \\ 0 & -1 & 0 & \dots & 0 & 0 & 1 & 0 & \dots & 0 & 0 & 1 & 0 & \dots & 0 \\ \vdots & & & & & & & \ddots & & & & & & & \vdots \\ 0 & \dots & 0 & -1 & 0 & 0 & \dots & 1 & 0 & 0 & \dots & 0 & 0 & 1 & 0 \\ 0 & \dots & 0 & 0 & -1 & 0 & \dots & 0 & 1 & 0 & \dots & 0 & 0 & 0 & 1 \\ 0 & \dots & 0 & 1 & -2 & 0 & \dots & -1 & 2 & 0 & \dots & 0 & 0 & -1 & 2 \end{bmatrix} \tag{13}$$

3. Contact algorithm

Similarly to the numerical strategy considered in [1], the present work relies on an explicit time integration scheme combined with a Lagrange multiplier-based contact treatment procedure [33]. Because the casing is now flexible, the complexity of the algorithm—detailed in Fig. 4—is significantly increased. In the following, the considered time step $n+1$ appears as a subscript of the quantities of interest. The superscript $*$ refers to the predicted quantities for which possible blade/casing contacts are ignored.

As pictured in Fig. 4, predicted displacements of the casing $\mathbf{v}_{c,n+1}^*$ and the impeller $\mathbf{v}_{i,n+1}^*$ are first computed and potential blade/casing contact forces are omitted. From these displacements, the absolute coordinates of the casing boundary nodes $\mathbf{P}_{n+1}^*$ are retrieved to compute the spline surface $\mathbf{Q}_{n+1}^*$ through Eq. (5). Then, a nonlinear iterative procedure, detailed in section 3.1, finds the impeller/casing distances $\mathbf{d}_{n+1}^*$ for each boundary node of the impeller and detects potential impeller/casing penetrations. From this point, two scenarii are to be considered: (1) one or more penetrations are detected, $\min(\mathbf{d}_{n+1}^*) < 0$, and non-admissible displacements

Figure 4. Time integration algorithm with unilateral contact conditions

must be corrected or (2) no penetration is detected, $\min(\mathbf{d}_{n+1}^*) > 0$, and the predicted displacements are admissible; time is then updated.

3.1 Impeller/casing distances $\mathbf{d}_{n+1}^*$

The computation of the impeller/casing distances $\mathbf{d}_{n+1}^*$ is the corner stone of the contact treatment procedure. At a given time step $n + 1$, the predicted position of the k^{th} impeller boundary node $\Gamma_{n+1}^{*,k}$ is pictured in Fig. 5. The formulation of a bicubic B-spline is

Figure 5. Newton-Raphson iterative procedure for the identification of the closest point on the spline from the bladed disk boundary node $\Gamma_{n+1}^{*,k}$.

such that the determination of the closest counterpart $\mathcal{S}^*(u_{n+1}^k, v_{n+1}^k)$ of $\Gamma_{n+1}^{*,k}$, see Fig. 5, which belongs to the spline contact surface, is a nonlinear algebraic problem which is addressed by the iterative Newton-Raphson procedure detailed in Fig. 6. Since the explicit time integration scheme features by nature small time steps, the result $\mathcal{S}(u_n^k, v_n^k)$ of this iterative procedure at the previous time step n provides an ideal starting point and convergence is reached within a handful number of iterations. For the very first time step, the initial guess is defined by the center of the closest patch that is easily determined through the distance of the impeller boundary node to the casing boundary nodes. The stop criterion mentioned in Fig. 6 is $\varepsilon_{\text{NR}} = 10^{-5}$; the sensitivity of the results to this parameter is assessed in section 3.3.

3.2 Contact matrices $\mathbf{MC}_{c,n+1}$ and $\mathbf{MC}_{i,n+1}$

When penetrations are detected, that is $\min(\mathbf{d}_{n+1}^*) < 0$, the correction of the displacements mentioned in Fig. 4 relies on the computation of contact matrices $\mathbf{MC}_{i,n+1}$ and $\mathbf{MC}_{c,n+1}$ respectively related to the impeller and the casing. These matrices are obtained following a four-step procedure:

1. computation of the outer normal vector $\mathbf{n}_{\text{out},n+1}^k$ to the spline contact surface at $\mathcal{S}^*(u_{n+1}^k, v_{n+1}^k)$, see Fig. 7:

$$\mathbf{n}_{\text{out},n+1}^k = -\frac{\overrightarrow{\partial \mathcal{S}^*(u_{n+1}^k, v_{n+1}^k)}}{\partial u} \wedge \frac{\overrightarrow{\partial \mathcal{S}^*(u_{n+1}^k, v_{n+1}^k)}}{\partial v} \quad (14)$$

2. computation of the tangential vector $\mathbf{t}_{n+1}^k$, see Fig. 7, to the spline contact surface at $\mathcal{S}^*(u_{n+1}^k, v_{n+1}^k)$:

$$\mathbf{t}_{n+1}^k = \mathbf{n}_{\text{out},n+1}^k \wedge \left(\mathbf{n}_{\text{out},n+1}^k \wedge \overrightarrow{\Gamma_n^k \Gamma_{n+1}^{*,k}} \right) \quad (15)$$

3. computation of the contact constraints matrices:

impeller: the contact constraints matrices of the impeller are obtained exactly as in [1, 27] and is thus not recalled for the sake of brevity.

casing: the spline surface governs the computation of the normal and tangential contact constraint matrices $\mathbf{VC}_{c,n+1}$ and $\mathbf{VCT}_{c,n+1}$:

- first of all, the patch $\mathcal{S}_{n+1}^{*,i,j}$ to which belongs the point $\mathcal{S}^*(u_{n+1}^k, v_{n+1}^k)$ is determined,
- the restriction of matrix $\mathbf{B}$ in Eq. (5) to the 16 control points $\mathcal{Q}_{n+1}^{i,j}$ involved in the definition of patch $\mathcal{S}_{n+1}^{*,i,j}$ is denoted $\hat{\mathbf{B}}$,

Figure 6. Bladed disk/casing distances algorithm

Figure 7. Determination of the $\mathbf{t}_{n+1}^k$ unit vector along which acts the tangential friction force

- from (u_{n+1}^k, v_{n+1}^k) and Eq. (6), the coefficient vector $\mathbf{c}^{i,j}$ to be applied on the control points $\mathcal{Q}^{i,j}$ so that:

$$\|\overrightarrow{\Gamma_{n+1}^{*,k} S^*(u_{n+1}^k, v_{n+1}^k)}\| = 0 \quad (16)$$

is computed,

- contact constraint matrices are then constructed:

$$\begin{aligned} \mathbf{VC}_{c,n+1} &= [\mathbf{VC}_{c,n+1}^1 \dots \mathbf{VC}_{c,n+1}^k \dots \mathbf{VC}_{c,n+1}^{NM}] \\ \mathbf{VCT}_{c,n+1} &= [\mathbf{VCT}_{c,n+1}^1 \dots \mathbf{VCT}_{c,n+1}^k \dots \mathbf{VCT}_{c,n+1}^{NM}] \end{aligned} \quad (17)$$

with:

$$\begin{aligned} \mathbf{VC}_{c,n+1}^k &= \hat{\mathbf{B}} \cdot \mathbf{c}^{i,j} \cdot \mathbf{n}_{\text{ext},n+1}^k \\ \mathbf{VCT}_{c,n+1}^k &= \hat{\mathbf{B}} \cdot \mathbf{c}^{i,j} \cdot (\mathbf{n}_{\text{ext},n+1}^k + \mu \mathbf{t}_{\text{ext},n+1}^k) \end{aligned} \quad (18)$$

4. Finally, the contact matrices for each structure are [33]:

$$\begin{aligned} \mathbf{MC}_{c,n+1} &= \mathbf{VC}_{c,n+1}^T \left[\frac{\mathbf{M}_c}{h^2} + \frac{\mathbf{D}_c}{2h} \right]^{-1} \mathbf{VCT}_{c,n+1} \\ \mathbf{MC}_{i,n+1} &= \mathbf{VC}_{i,n+1}^T \left[\frac{\mathbf{M}_i}{h^2} + \frac{\mathbf{D}_i}{2h} \right]^{-1} \mathbf{VCT}_{i,n+1} \end{aligned} \quad (19)$$

and the displacement fields are corrected and updated as explained in Fig. 4.

3.3 Numerical validation

The exposed numerical procedure is highly nonlinear and thus requires a thorough validation. The main parameters include: (1) the stop criterion ε_{NR} of the Newton-Raphson procedure given in section 3.1, (2) the time step h of the time integration scheme, (3) the friction coefficient μ in Eq. (18), (4) the basis used in the computation of the reduced-order models of the casing and the impeller and (5) the M boundary nodes retained on each sector of the casing describing the contact interface.

3.3.1 Stop criterion ε_{NR}

Two values of the stopping criterion ε_{NR} are considered in this section: the default $\varepsilon_{\text{NR}} = 10^{-5}$ and $\varepsilon_{\text{NR}} = 10^{-10}$ to accurately check for convergence. Displacements of the casing and the impeller are drawn in Figs. 8(a) and 8(b), respectively. The results for both stop criteria are perfectly superimposed. In the context of 3D finite element models with linear elasticity considered in this study,

Figure 8. Sensitivity to stopping criterion in Newton-Raphson algorithm: $\varepsilon_{\text{NR}} = 10^{-5}$ (—) and $\varepsilon_{\text{NR}} = 10^{-10}$ (---): (a) radial displacement of the leading edge of impeller sector 2, (b) radial displacement of a boundary node of the casing

the expected levels of vibration remain low. Typically, the radial displacement of a casing boundary node is two to three orders of magnitude smaller than the casing diameter which implies that the curvature of one spline patch has a negligible effect. Were larger radial displacements to be considered, the proposed strategy would still be efficient but a much lower stopping criterion would be required for converged results.

3.3.2 Friction forces and numerical sensitivity

Friction is usually sensitive from a numerical standpoint. Two numerical simulations are carried out, one with no friction $\mu = 0$ and one with a very low friction coefficient $\mu = 0.01$. Associated results are depicted in Figs. 9. The point is to ensure that the introduction of friction does not generate numerical instabilities. Due to friction, the results for each simulation are obviously slightly different yet almost identical which emphasizes that there is no numerical instability related to μ . As the friction coefficient increases, significant discrepancies shall arise.

3.3.3 Convergence analysis

The convergence of the results with respect to the other numerical parameters such as the time step h and the dimension of modal reduction bases were assessed but are not detailed. Convergence is observed with respect to each of these parameters and the numerical simulations carried out in the following consider $h = 10^{-7}$ s, and ten modes are retained for each nodal diameter of the

Figure 9. Sensitivity to friction: $\mu = 0$ (—) and $\mu = 0.01$ (---): (a) tangential displacement of the leading edge of impeller sector 2, (b) radial displacement of a boundary node of the casing

casing and the impeller in their respective reduction basis, see [1] for more details. The number M of boundary nodes for each sector of the casing significantly influences the results but convergence is found for $M \geq 5$. It should be mentioned here that increasing M has a fairly low impact on the computation times (multiplying M by 2 leads to an increase of computation times of about 20 %).

Other tests carried out in order to validate the numerical strategy feature the respect of symmetry in the displacements when a symmetric contact scenario is considered. Finally, the residual penetrations within the casing after correction of the displacements are systematically negligible (about 8 orders of magnitude lower than the level of vibration of the associated boundary node).

4. Abradable coating modeling

In addition to blade/casing unilateral contact and friction, the proposed developments also include the modeling of abradable coating, a sacrificial material deposited on the casing contact surface in order to mitigate blade/casing contacts. The removal of this material is accounted for through a residual plastic compression $\Delta\epsilon_p$ of the abradable elements as presented in [24]. By choice, one element is used over the thickness of the abradable layer which is uniform over the casing contact surface. With this relatively simple model a real-time update of the contact interface is realized and recent numerical investigations have highlighted its relevance for the modeling of the interaction forces, be it abradable coating removal or unilateral contact, for both full-scale tests in turbomachines [34] and smaller experimental set-up [35]. Numerically, the abradable elements are rigidly attached to the spline surface as depicted in Fig. 10.

Figure 10. Impeller sector with abradable coating (yellow) and supporting spline surface (green).

4.1 General algorithm

Note: in the following, two contact scenarii are distinguished: the impeller may penetrate (1) the coating or (2) the casing. In the case the impeller penetrates the casing, it is implied that the abrasible coating has been locally removed.

The algorithm embedding abrasible coating removal is presented in Fig. 11 and generalizes the algorithm in Fig. 4. Once impeller/casing distances $\mathbf{d}_{n+1}^*$ are computed, possible impeller/casing penetrations are dealt with following the procedure in Fig. 4. If a boundary node of the impeller penetrates the casing, the surrounding abrasible coating is automatically removed: the plastic deformation of the related abrasible elements is set to the initial thickness of the coating $\Delta\epsilon_p = e_{abr}$. Consequently, the node is quarantined for the current time step, in other words, it is excluded from the blade/abrasible coating penetration detection procedure.

Figure 11. Time integration algorithm with contact treatment and abrasible coating management.

For each boundary node of the impeller, the distance to the abrasible coating $\mathbf{d}_{n+1}^{*,abr}$ is computed from $\mathbf{d}_{n+1}^*$ and the local thickness of the abrasible coating $e_{abr} - \Delta\epsilon_p$. If $\min(\mathbf{d}_{n+1}^{*,abr}) < 0$, the plastic constitutive law described in [24] yields the contact forces λ_{n+1}^{abr} . The computation of the contact constraints matrices and the contact matrices is identical to the procedure in section 3.2.

4.2 Validation and convergence

Numerical investigations similar to the ones detailed in section 3.3 are not recalled here but identical conclusions are obtained.

4.2.1 Spatial convergence with respect to the number of abradable elements

Convergence is checked against the number η of abradable elements: $\eta = 600$, 3000, 6000, and 12000. This parameter has low to no impact on the computation cost of the procedure, no significant time differences were found. The radial displacement of the impeller sector 1 leading edge is pictured with the final abradable wear profiles in Fig. 12. Minor differences are visible between displacements and contact forces for various η in Figs. 12(a), 12(b), and 12(c). However, the number of abradable elements has a strong influence on the coating wear levels as depicted in Fig. 12(d). Ultimately, for $\eta = 6000$ and $\eta = 12000$, results are almost perfectly superimposed for all quantities of interest and $\eta = 6000$ abradable elements are used in the following.

Figure 12. Convergence analysis with respect to the number of abradable elements η : $\eta = 600$ (—), $\eta = 3000$ (—), $\eta = 6000$ (—) and $\eta = 12000$ (—), (a) radial displacement of the impeller sector 1 leading edge, (b) radial displacement close to the casing trailing edge, (c) radial contact force on the impeller sector 1 trailing edge, (d) abradable removal profile.

4.2.2 Localized removal of the abradable coating

As mentioned previously, the solution method is compatible with hybrid contact scenarios where the abradable coating may be locally completely removed. Such interaction scenario is encouraged by reducing the abradable coating thickness ($e_{abr} = 0.15$ compared to typical values $e_{abr} = 2$ or 3). The initial clearance between the impeller and the casing at the trailing edge is set to zero so that contacts and removal are activated from the very beginning of the simulation as the casing is progressively distorted. Results are pictured in Fig. 13. Fig. 13(a) indicates that the abradable coating is locally totally removed since a portion of the distances separating a few blades and the casing reaches zero. Related radial displacements at the trailing edge of each sector are plotted in Fig. 13(b). The corresponding contact forces depicted in Fig. 13(c) can be classified as follows: the ones stemming from the plastic constitutive law when the abradable coating is impacted (—) and the ones computed with Lagrange multipliers when direct unilateral contact is active after the abradable coating has been completely worn off (—). Evidence of total abradable removal is also displayed in Fig. 13(d) where the wear level reaches the initial coating thickness e_{abr} .

5. Case study 1: two-lobe distortion of the casing

In this case study, a progressive loading is applied for $t \in [0; t_f]$ along the casing circumference at the trailing edge. The deformed casing features two dominant symmetric contact areas with respect to the axis of rotation. For $t > t_f$, the two structures are left free to interact while the impeller rotates at the angular speed Ω . The choice is made to initiate contact at the trailing edge where the casing exhibits high flexibility, far from the clamped nodes at the leading edge, shown in Fig. 1. Exemplary, the displacement and stress fields within the impeller and the casing are depicted in Figs. 14 and 15 respectively.

Figure 13. Locally full removal of the abrasible coating: (a) distances between the trailing edge of each sector of the impeller and the casing, (b) radial displacements of the trailing edge of each sector, (c) radial contact forces on the trailing edge of each sector when impacting the abrasible coating (—) and with direct contact on the casing (—), (d) trailing edge wear level on the casing.

In agreement with the symmetry of the loading applied on the casing, the perfect symmetry of these fields is noticeable and underlines the accuracy of the employed numerical strategy. Also, while contact is initiated at the trailing edge, Fig. 14 undoubtedly indicates that the largest displacements arise in the neighbourhood of the leading edge, where the greater blade length yields higher amplitude displacements. Significant stresses are found within the impeller both in the blades and the disk sections.

5.1 Influence of friction

The influence of the friction coefficient μ is assessed considering three values: $\mu = 0, 0.15$, and 0.3 . Related results are pictured in Fig. 16. First of all, it is noticeable that the lower μ , the higher the wear level in the abrasible coating, as pictured in Fig. 16(d). For the angular speed of interest Ω , μ has no effect on the casing displacements in Fig. 16(b). However, no clear conclusion can be drawn from Fig. 16(c) concerning the amplitude of the contact forces.

5.2 Sensitivity to the mechanical properties of the abrasible coating

Previous work illustrated the key role of the mechanical properties of the abrasible coating in the rotor/stator interactions [34]. From the nominal values of the Young's and plastic moduli E_n and K_n obtained from empirical data, two extreme scenarii are considered: (1) a lower bound $E = E_n/10$, $K = K_n/10$ and (2) an upper bound $E = 10E_n$, $K = 10K_n$. The changes in the mechanical properties have a visible effect on the displacements of both the impeller and the casing, as pictured in Figs. 17(a) and 17(b). For low Young's and plastic moduli (—), the amplitude of the boundary nodes displacements becomes lower for the impeller and higher for the casing. In that case, the removal of the coating is made easier and thus generates smaller contact forces on the impeller. On its side, the casing is less constrained in its vibration for $t > t_f$ after the external loading is not applied anymore.

The conclusions drawn in this section depend on Ω and results may be different in the vicinity of a critical speed as explained in [1].

5.3 Vibratory energy analysis

As mentioned earlier, the casing features two symmetric privileged contact areas induced by the external loading exerted on the casing. Analytical considerations exposed in [1] predict that odd nodal diameters have a negligible role in the vibratory response of the system. However, the aliasing effect may generate a non negligible participation of all even nodal diameters. To confirm these predictions, the methodology described in [1] could be implemented through harmonic tracking or 2D Fourier transforms, for instance. In order to present other post-processing options, our interest is directed on the impeller strain energy $\mathcal{E}_i(t)$ and its participation within each of

Figure 14. Impeller during the interaction: (a) displacement field at $t = 0.3 < t_f$, (b) Von Mises stress field at $t = 0.3 < t_f$, (c) displacement field at $t = 1.5 > t_f$, (d) Von Mises stress field at $t = 1.5 > t_f$. Displacements are magnified for better readability.

the six nodal diameters of the structure. If $\mathbf{v}_i(t)$ stands for the displacement field of the impeller and $\mathbf{K}_i$ for its stiffness matrix, then:

$$\mathcal{E}_i(t) = \frac{1}{2} \mathbf{v}_i(t)^\top \mathbf{K}_i \mathbf{v}_i(t) \quad (20)$$

The displacement $\mathbf{v}_i(t)$ can be expanded as a finite sum of free vibration modes ϕ_p :

$$\exists q_p(t), \quad p = 1, \dots, n, \quad \mathbf{v}_i(t) = \sum_{p=1}^n q_p(t) \phi_p \quad (21)$$

After sorting the free vibration modes according to their number of nodal diameters n_d , the strain energy associated to each nodal diameter takes the form:

$$\mathcal{E}(n_d = j, t) = \frac{1}{2} \left[\sum_{p, n_d(\phi_p)=j} q_p(t) \phi_p \right]^\top \mathbf{K}_i \left[\sum_{p, n_d(\phi_p)=j} q_p(t) \phi_p \right] \quad (22)$$

The strain energy $\mathcal{E}_i$ is depicted with all strain energies related to a given nodal diameter $\mathcal{E}(n_d)$ in Fig. 18. The strain energies associated with odd nodal diameters are found negligible with respect to those associated with even nodal diameters. Dominating nodal diameters 0 and 2 and a non-negligible participation of nodal diameter $n_d = 4$ are found, which is consistent with the symmetry of the interaction scenario.

6. Case study 2: investigations around a critical speed

The linear interaction criterion introduced in [1] can predict potential critical angular speeds. In particular, an angular critical speed is predicted for $\Omega = \Omega_1^5 \simeq 0.49$ as pictured in Fig. 19. This interaction point supposedly involves two 5-nodal diameter free vibration modes: accordingly, the casing is now distorted on a five-nodal diameter shape. Because of contact-induced stiffening, it is assumed that the interaction may actually arise for slightly higher angular speeds than Ω_1^5 . Numerical simulations are carried out from $\Omega = 0.48$ to $\Omega = 0.58$. The Fourier transform of the time responses obtained for each angular speed is depicted in Fig. 20. It is remarkable that

Figure 15. Casing during the interaction: (a) displacement field at $t = 0.3 < t_f$, (b) Von Mises stress field at $t = 0.3 < t_f$, (c) displacement field at $t = 1.5 > t_f$, (d) Von Mises stress field at $t = 1.5 > t_f$. Displacements are magnified for better readability.

no significant amplitudes of vibration is found in the vicinity of Ω_1^5 even though the interaction condition is satisfied. In order to clarify this unexpected absence of vibratory resonance, modeshapes are provided in Fig. 21. The comparison highlights a geometric incompatibility: significant deformations are localized around the leading edge for the impeller and around the trailing edge for the casing. It seems very improbable to see these two free-vibration modes dangerously interact through contact.

This very brief example shows a limitation of the linear interaction condition. As mentioned in [1], this criterion fails to predict super- or sub-harmonics related interactions. The criterion also predicts unimportant critical angular speeds as the modal shapes of the two structures are not geometrically compatible. As a result, the proposed numerical strategy advantageously complements the linear interaction condition by providing additional insight on the predicted critical angular speeds. It also brings the foundation for the development of optimized impellers robust to contact conditions.

7. Conclusion

The numerical strategy exposed in [1] is here extended to rotor/stator interactions involving a flexible casing, full three-dimensional friction forces and the modeling of the abradable coating deposited on the casing. The related algorithms are detailed and validated. Their versatility is promising and the presented numerical strategy is applicable to a variety of rotor/stator systems potentially undergoing interaction phenomena from rubbing to modal interaction. The qualitative analysis exposed in [1] is complemented by the quantitative developments of the present work.

The proposed solution method allows for the numerical simulation of various interaction scenarii where abradable coating removal may be accounted for along the flexible casing. Accounting for the casing flexibility allows for broadening the scope of simulated interactions from rubbing phenomena to modal interaction and detecting critical angular speeds for each type of interaction. More specifically, hybrid scenarii featuring a localized yet complete removal of the coating are also explored. It is shown that the linear interaction condition, which stands as an important guideline for the design of impellers and casings, may be advantageously complemented by the numerical strategy exposed in both [1] and the present article: (1) super- and sub-harmonics related interactions that are not captured by this criterion but may be accurately predicted numerically instead and (2) the relevance of linearly predicted

Figure 16. Influence of the friction coefficient: $\mu = 0$ (—), $\mu = 0.15$ (—) and $\mu = 0.3$ (—): (a) radial displacement of the impeller sector 1 trailing edge, (b) radial displacement at the casing trailing edge, (c) radial contact force on the impeller sector 1 trailing edge, (d) abradable removal profile.

critical angular speed may be assessed. As shown in the last case study exposed in this article, a critical speed may be predicted for free vibration modes that are not geometrically compatible and thus, may not interact.

Figure 17. Sensitivity to the abradable coating properties: $(E_n/10, K_n/10)$ (—), (E_n, K_n) (—) and $(10E_n, 10K_n)$ (—): (a) radial displacement of the impeller sector 1 trailing edge, (b) radial displacement at the casing trailing edge, (c) radial contact force on the impeller sector 1 trailing edge, (d) abradable removal profile.

Figure 18. Strain energies: $\mathcal{E}_i$ (—), $\mathcal{E}(n_d = 0)$ (—), $\mathcal{E}(n_d = 1)$ (—), $\mathcal{E}(n_d = 2)$ (—), $\mathcal{E}(n_d = 4)$ (—), $\mathcal{E}(n_d = 1) + \mathcal{E}(n_d = 3) + \mathcal{E}(n_d = 5)$ (---),

Figure 19. Absolute frame Campbell diagram limited to one five-nodal diameter mode of the impeller (—) and the casing (---).

Figure 20. Fourier transform of the impeller sector 1 radial displacement around Ω_1^5

Figure 21. Modal shapes of the investigated 5-nodal diameter free vibration modes.
