Multiple Sensor Fusion and Classification for Moving Object Detection and Tracking

R. Omar Chavez-Garcia and Olivier Aycard

Abstract—The accurate detection and classification of moving objects is a critical aspect of Advanced Driver Assistance Systems (ADAS). We believe that by including the objects classification from multiple sensors detections as a key component of the object’s representation and the perception process, we can improve the perceived model of the environment. First, we define a composite object representation to include class information in the core object’s description. Second, we propose a complete perception fusion architecture based on the Evidential framework to solve the Detection and Tracking of Moving Objects (DATMO) problem by integrating the composite representation and uncertainty management. Finally, we integrate our fusion approach in a real-time application inside a vehicle demonstrator from the interactIVe IP European project which includes three main components: SLAM and DATMO which generates a map of the environment while simultaneously localizing the vehicle within the map given all the measurements from sensors; and DATMO which detects and tracks the moving objects surrounding the vehicle and estimates their future behaviour. Fig. 1 shows the main components of the perception task.

Management of incomplete information is an important requirement for perception systems. Incomplete information can be originated from sensor-related reasons, such as calibration issues, hardware malfunctions, uncertain detections and asynchronous scans; or from scene perturbations, like occlusions, weather issues and object shifting. The tracking process assumes that its inputs correspond uniquely to moving objects, and then focus on data association and tracking problems. However, in most of the real outdoor scenarios, these inputs include non-moving detections, such as noisy detections or static objects. Correctly detecting moving objects is a critical aspect of a moving object tracking system. Usually, many sensors are part of such systems.

Knowing the class of objects surrounding the ego-vehicle provides a better understanding of driving situations. Classification is seen as a separate task within the DATMO task or as an aggregate information for the final perception output. Classification can help to enrich the detection stage by including information from different sensor views of the environment, e.g. impact points provided by lidar and image patches provided by camera. Evidence about the class of objects can provide hints to discriminate, confirm and question data associations. Moreover, knowing the class of a moving object benefits the motion model learning and tracking. We believe that classification information about objects of interest gathered from different sensors at early stages can improve their detection and tracking, by reducing false positive detections and mis-classifications.

Regarding the state of the art approaches, we assume the SLAM stage as a solved task, and focus on the detection, classification and tracking of moving objects. Precisely, we include object’s class as the key compo-
Fusion at detection level focus on gathering and combining early data from sensor detections to reduce the number of mis-detections that can lead to false tracks. Several works focus on data redundancy from active and passive sensors, and follow physical or learning constrains to increase the certainty of object detection. These works do not include all the available kinetic and appearance information [6], [7]. Moreover, at this level, appearance information from sensor measurements is not considered as important as the kinetic data to discriminate moving and static objects [8].

When classification is considered as an independent module inside the perception solution, this is often implemented as a single-class (e.g., only classifies pedestrians) or single-sensor based classification process [2], [5]. This excludes valuable discriminative data from multiple sensor views that can generate multi-class modules. Research perspectives point-out the improvement of the data association and tracking tasks as a direct enhancement when classification information is managed at early levels of perception [5], [2], [9].

The most common approaches for multi-sensor fusion are based on probabilistic methods [2], [1]. However, methods based on the Evidential framework proposed an alternative not only to multi-sensor fusion but to many modules of vehicle perception [7], [5], [9]. These methods highlight the importance of incomplete and imprecise information which is not usually present in the probabilistic approaches.

An advantage of our fusion approach at the detection level is that the description of the objects can be enhanced by adding knowledge from different sensor sources. For example, lidar data can give a good estimation of the distance to the object and its visible size. In addition, classification information, usually obtained from camera images, may allow to make assumptions about the class of detected object. An early enrichment of objects’ description could allow the reduction of the number of false detections and to involve classification as a key element rather than only an add-on to the perception output.

III. EVIDENTIAL FRAMEWORK

The Evidential framework is a generalization of the Bayesian framework of subjective probability [10]. Evidential theory (ET) allows us to have degrees of belief for a related question according to the available evidence. ET represents the world in a set of mutually exclusive propositions known as the frame of discernment (Ω). It uses belief functions to distribute the evidence about the propositions over 2Ω. The distribution of mass beliefs is done by the function \( m : 2Ω → [0,1] \), also known as Basic Belief Assignment (BBA):

\[
m(Ω) = 0, \quad \sum_{A ∈ Ω} m(A) = 1. \quad (1)
\]
Yager’s rule combines two sources of evidence while avoiding counter-intuitive results, which are present when there is a considerable degree of conflict \((m(\emptyset))\). In this rule, the conflict value is distributed among all the elements of the frame of discernment rather than only the elements with intersections of the combining masses:

\[
m(A) = \sum_{X_i \cap Y_j = A} m_1(X_i)m_2(Y_j), \quad A \neq \emptyset, A \neq \Omega,
\]

\[
m(\Omega) = \sum_{X_i \cap Y_j = \Omega} m_1(X_i)m_2(Y_j) + \sum_{X_i \cap Y_j = \emptyset} m_1(X_i)m_2(Y_j).
\]

A. Evidential Theory for Vehicle perception

ET has the ability to represent incomplete evidence, total ignorance and the lack of a need for a priori probabilities. We can encode implicit knowledge in the definition of the structure of the frame of discernment. In addition, discounting factors are an important mechanism to integrate the reliability of the sources of evidence, such as sensor performance. Moreover, combination rules are useful tools that integrate information from different bodies of evidence. Late stages of intelligent systems, such as reasoning & decision, can integrate evidence distributions into the decision making process [10].

When the number of hypotheses is large, ET becomes less computationally tractable because the belief is distributed over the power set of all the hypotheses, \(2^\Omega\). However, the application domain may allow to make assumptions to transform \(\Omega\) into a reduced version of the set of possible hypotheses.

IV. Vehicle demonstrator

We used the CRF (Fiat Research Center) demonstrator, from the the interactIVe European project, to obtain datasets from different driving scenarios. In order to accomplish the Continuous Support functionalities, the Lancia Delta car (see Fig. [1]) is equipped with processing units, driver interaction components, and the following front-facing set of sensors: TRW TCAM+ camera gathers B&W images and has a FOV of \(\pm 21^\circ\); TRW AC100 medium range radar provides information about moving targets. It has a detection range up to 150m, velocity range up to 250kph, FOV of \(\pm 12^\circ\) (close range) or \(\pm 8^\circ\) (medium range), and angular accuracy of 0.5\(^\circ\); and an IBEO Lux laser scanner provides a 2D list of impact points, it has a range up to 200m with an angular and distance resolution of 0.125\(^\circ\) and 4cm respectively, and a FOV of 110\(^\circ\).

V. Software architecture

Our contribution inside the interactIVe project takes place at the Perception System (PS) that aims at improving the efficiency and quality of sensor data fusion, focusing on object detection and classification. In the PS, multiple functions are developed for continuous driver support, and also for executing active interventions for collision avoidance and collision mitigation.

Fig. [2] shows the schematic of our proposed PS, and the interaction between the detection and classification modules. The PS aims at detecting, classifying and tracking a set of moving objects of interest that may appear in front of the vehicle. The inputs of the fusion module are three lists of detected objects from three sensors: lidar, radar and camera. Each object is represented by its position, size and an evidence distribution of class hypotheses. Class information is obtained from the shape, relative speed and visual appearance of the detections. Lidar and radar data are used to perform moving object detection and, in cooperation with image data they extract object classification. Three list of composite object descriptions are taken by our fusion approach and delivered to our tracking algorithm. The final output of the fusion method comprises a fused list of object detections that will be used for the tracking module to estimate the moving object states and deliver the final output of our DATMO solution.

VI. Moving object detection

Here, we review the moving object detection methods for each sensor. In Section [VII], we describe the process for object classification.
A. LIDAR processing

We consider the LIDAR (Light Detection And Ranging) scanner as the main sensor in our configuration due to its high resolution and accuracy to detect obstacles. In addition, it powers the SLAM component of our perception solution. The main goal of the lidar processing is to get precise measurements of the shape of the moving obstacles in front of the vehicle.

1) SLAM component solution: Although our main contributions are focused on the DATM0 component, we solve the SLAM component in order to obtain the map and the vehicle's localization. Following the idea proposed in [1], we employ lidar data \((z_{1:t})\) for populating a two-dimensional Bayesian occupancy grid map. Each cell in the map \(M\) is associated with a measurement indicating the probability that the cell is occupied or not by an obstacle. Vehicle's location is found by a Maximum a posteriori estimation of the moving obstacles in front of the vehicle.

\[
\omega^* = \arg \max_{\omega \in \Omega} P(\omega | z_{1:t}), \quad \text{for} \quad P(\omega | z_{1:t}) \propto P(w)P(z_{1:t} | \omega)
\]

(3)

2) LIDAR-based Detection: As described [1], [12], we focus on identifying the inconsistencies between free and occupied cells within the grid map \(M\) while incrementally building such map. If an occupied measurement is detected on a location previously set as free, then it belongs to a moving object. If a free measurement is observed on a location previously occupied then it probably belongs to a static object.

Using a distance-based clustering process we identify clouds of cells that could belong to moving objects. This process provides information about the visible shape of the possible moving object, an estimation of its size, and the distance to the object. Fig. 5 shows an example of the evolution of the lidar-based moving object detection process. Measurements detected as parts of a moving object are not used to update the map in SLAM.

B. Camera images

In order to extract information regarding the visual appearance of the objects from camera images, we have to be able to represent these objects using visual features.

1) Visual representation: The Histograms of Oriented Gradients (HOG) descriptor has shown promising results in vehicle and pedestrian detection [13]. We decided to take this descriptor as the core of our vehicle and pedestrian visual representation. The goal of object representation is to generate visual descriptors of areas of the image to be used in future stages to determine whether these areas contain an object of interest or not.

We propose sparse version of HOG descriptor (S-HOG) that focuses on specific areas of an image patch. This allows us to reduce the common high-dimensional HOG descriptor [12]. Fig. 6 illustrates some of the blocks we have selected to generate the descriptors for different object classes: pedestrian, bike, car and truck. These blocks correspond to meaningful regions of the object (e.g., head, shoulder and legs for pedestrians). To accelerate S-HOG feature computation, we followed an integral image scheme [14].

![Figure 6. Informative blocks for each object class patch, from left to right: pedestrian, car, and truck. Histograms of gradients are computed over these sparse blocks and concatenated to form S-HOG descriptors. Average size of the descriptors for pedestrians, bikes, cars and trucks are 216, 216, 288 and 288 respectively.](image)

2) Object classification: Due to performance constraints, we did not implement a visual-based moving object detection. We used the regions of interest (ROI) provided by lidar detection to focus on specific regions of the image. For each ROI, visual features are extracted, and a classifier is applied to decide if an object of interest is inside the ROI. The choice of the classifier has a substantial impact on the resulting speed and quality. We implemented a boosting-based learning algorithm, discrete Adaboost [15]. It combines many weak classifiers to form a powerful one, where weak classifiers are only required to perform better than chance.

For each class of interest (pedestrian, bike, car, truck), a binary classifier was trained to identify object (positive) and non-object (negative) patches. For the off-line training stage, positive images were collected from public (such as the Daimler dataset) and manually labelled datasets containing objects of interest from different object's viewpoints (frontal, rear, profile) [9].

Off-line classifiers are used by the on-line object classification stage in a sliding-window scheme. Fig. 7 shows examples of the pedestrian and car detection results (green and red boxes respectively) before merging into the final objects. We estimate the confidence of object classification for each possible object. Generally, the greater the number of positive areas (containing an
object of interest), the higher the confidence that the object belongs to that specific class.

C. Radar targets

The radar sensor uses a built-in mechanism to detect moving obstacles (targets), specially those with a cross-section similar to a car. The list of $n$ targets is delivered as input to the perception approach. Each element of the list includes the range, azimuth and relative speed of the detected target. As the sensor will produce a return for each object with a significant radar cross section, targets may correspond to static objects or other moving obstacles, producing false positives. In a similar way, weak objects like pedestrians can not always be detected, consequently producing mis-detections. Due to different dynamics defining the objects of interest, we track every target using and Interactive Multiple Model (IMM) represented by constant velocity, constant acceleration and turning models. IMM provides a trade-off between a Generalized Pseudo Bayesian method of first (GPB1) and second (GPB2) degree [16], [3]. It only computes $k$ Gaussians as in GPB1 but it still having as output an mixture of $k$ Gaussians as in GPB2. Data association between targets is achieved by a prunned Multi Hypothesis Tracking approach.

VII. MOVING OBJECT CLASSIFICATION

We enhanced the common kinetic representation by including class information within fusion at the detection level. This information can help to improve detection associations, better estimate object’s motion, and reduce the number of false tracks. However, at detection level, there is not enough certainty about the object’s class and keeping only one class hypothesis disables the possibility of rectifying a premature decision.

Our composite representation is formed by two parts: kinetic + appearance. The former includes position and shape information in a two dimensional space, inferred from the moving object detection process. The latter includes an evidence distribution $m(2\Omega)$ for all possible class hypotheses, where $\Omega = \{\text{pedestrian}, \text{bike}, \text{car}, \text{truck}\}$ is the frame of discernment representing the classes of interest. This representation is used by the fusion approach to deliver a fused list of object detections, and to perform tracking.

![Figure 7. Examples of successful detection of pedestrians (left) and cars (right) from camera images.](image)

A. Lidar sensor

The first part of the object representation can be obtained by analysing the shape of the detected moving objects. In the case of large detections this object is modelled by a box $\{x, y, w, l, c\}$, where $x$ and $y$ are the center of the box, $w$ and $l$ are the width and length according to the class of object $c$. For small detections (mainly pedestrians) a point model $\{x, y, c\}$ is used, where $x$, $y$ and $c$ represent the object center and class of the object, respectively. The position and size of the object is obtained by measuring the detected objects in the 2D occupancy grid. The class of the object is inferred from the visible size of the object and follows a fixed fitting-model approach. However, no precise classification decision can be made due to the temporary visibility of the moving objects. For example, if the width of a detected object is less than a threshold $\omega_{\text{small}}$, we may think the object is a pedestrian or a bike but we are not sure of the real size of the object.

To define the typical size of the classes of interest, we used a priori knowledge from the distribution of the physical dimensions of several passenger cars, trucks and motorbikes sold in Europe [17]. However, instead of keeping only one class decision, we define a basic belief assignment $m_1(A)$ (Equation 4) for each $A \in \Omega$, which describes an evidence distribution for the class of the moving object detected by lidar. We include class-related factors ($\alpha_p, \alpha_p, \alpha_c$ and $\alpha_t$) to represent the lidar’s performance to detect pedestrians, bikes, cars and trucks, respectively. Also we use discounting factors ($\gamma_b$ and $\gamma_c$) to indicate the uncertainty of the lidar processing for mis-detecting a bike or car.

When a bike is detected, due to visibility issues the detected object can still be a part of a car or a truck, for that reason evidence is also put in $\{b, c, t\}$. For the same reason, when a truck is detected, we are almost sure it cannot be a smaller object. In all the cases, the ignorance hypothesis $\Omega$ represents the lack of knowledge and the general uncertainty about the class.

$$m_1(A) = \begin{cases} m_1(\{p\}) = \alpha_p & \text{if class} = p \\ m_1(\Omega) = 1 - \alpha_p \\ m_1(\{b\}) = \gamma_b \alpha_b & \text{if class} = b \\ m_1(\{b, c, t\}) = \gamma_b (1 - \alpha_b) \\ m_1(\Omega) = 1 - \gamma_b \\ m_1(\{c\}) = \gamma_c \alpha_c & \text{if class} = c \\ m_1(\{c, t\}) = \gamma_c (1 - \alpha_c) \\ m_1(\Omega) = 1 - \gamma_c \\ m_1(\{t\}) = \alpha_t & \text{if class} = t \\ m_1(\Omega) = 1 - \alpha_t \end{cases}$$

B. Camera sensor

Camera images offer discriminative visual information which leads to obtain another evidence distribution for the object classes. We follow the image processing described in Section VI-B2. For hypotheses generation, we first build a S-HOG descriptor for each section of the
image we want to classify. For hypothesis verification, we use the built classifiers to classify the different objects.

The camera-based classification generates several sub regions inside each ROI, provided by lidar, in order to cover many possible scale and size configurations. Sometimes a ROI can contain more than one object of interest. Once we have obtained the object classification for each ROI, we generate a basic belief assignment for each object detected for camera processing, where \(a_p, a_c\) and \(a_t\) are confidence factors and \(c_e\) represents the camera sensor’s precision.

\[
\begin{align*}
    m_e(\{p\}) &= a_p c_e & \text{if class = p} \\
m_e(\{p, b\}) &= a_p (1 - c_e) \\
m_e(\Omega) &= 1 - a_p \\
m_e(\{b\}) &= a_b c_e & \text{if class = b} \\
m_e(\{p, b\}) &= a_b (1 - c_e) \\
m_e(\Omega) &= 1 - a_b \\
m_e(\{c\}) &= a_c c_e & \text{if class = c} \\
m_e(\{c, t\}) &= a_c (1 - c_e) \\
m_e(\Omega) &= 1 - a_c \\
m_e(\{t\}) &= a_t c_e & \text{if class = t} \\
m_e(\{c, t\}) &= a_t (1 - c_e) \\
m_e(\Omega) &= 1 - a_t
\end{align*}
\]

\[
m_e(A) = \begin{cases} 
    m_e(\{p\}) = a_p c_e & \text{if object speed} < S_p \\
m_e(\{p, b\}) = 1 - a_p & \text{if object speed} > S_p \\
m_e(\Omega) = 1 - \beta \end{cases}
\]

C. Radar sensor

Radar targets are considered as preliminary moving object detections. Therefore, to obtain the object’s class, we use the relative target speed deliver by the sensor. Speed threshold \(S_p\) is statistically estimated using recorded data from the slowest scenario for vehicles, urban areas. We apply the basic belief assignment \(m_r\) (Equation 6), where \(\alpha\) and \(\beta\) are confidence factors for specific classes.

\[
m_r(\{p\}) = \alpha \\
m_r(\{p, b\}) = 1 - \alpha \\
m_r(\Omega) = 1 - \beta \\
m_r(\{c\}) = \alpha c_e \\
m_r(\{c, t\}) = \alpha (1 - c_e) \\
m_r(\Omega) = 1 - \alpha \\
m_r(\{t\}) = \alpha c_e \\
m_r(\{c, t\}) = \alpha (1 - c_e) \\
m_r(\Omega) = 1 - \alpha
\]

VIII. Fusion Approach

Once we have performed moving object detection for each sensor input, and defined a composite object representation, the next task is the fusion of object detections and tracking. We propose a multi-sensor fusion framework placed at the detection level. Although this approach is presented using three main sensors, it can be extended to work with more sources of evidence by defining extra detection modules that are able to deliver the object representation previously defined.

A. Data association

When working with many sources of evidence, as in the object detection level, it is important to consider the problem of finding which object detections are related among the different lists of detections provided by the sensors (sources of evidence).

The combination of information at the detection level has the advantage of increasing the reliability of the detection result by reducing the influence of inaccurate, uncertain, incomplete, or conflicting information from sensor measurements or object classification modules.

Let us consider two sources of evidence \(S_1\) and \(S_2\). Each of these sources provides a list of detections \(A = \{a_1, a_2, ..., a_m\}\) and \(B = \{b_1, b_2, ..., b_n\}\), respectively. In order to combine the information of these sources we need to find the associations between the detections in \(A\) and \(B\). All possible associations can be expressed as a matrix of magnitude \(|A \times B|\), where each cell represents the evidence \(m_{a_i,b_j}\) about the association of the elements \(a_i\) and \(b_j\) for \(i \leq |A|\) and \(j \leq |B|\). We can define three propositions regarding the possible association \(P(a_i,b_j)\):

- \(1\) : if \(a_i\) and \(b_j\) are the same object.
- \(0\) : if \(a_i\) and \(b_j\) are not the same object.
- \(\Omega\) : ignorance about the association \((a_i,b_j)\).

Let us define \(\Omega_d = \{1,0\}\) as the frame of discernment to represent the aforementioned propositions. Therefore, \(m_{a_i,b_j}(\{1\})\) and \(m_{a_i,b_j}(\{0\})\) quantify the evidence supporting the proposition \(P(a_i,b_j) = 1\) and \(P(a_i,b_j) = 0\) respectively, and \(m_{a_i,b_j}(\{1,0\})\) stands for the ignorance, i.e., evidence that cannot support the other propositions. These propositions can be addressed by finding similarity measures between detections in \(A\) and \(B\).

Sensors \(S_1\) and \(S_2\) can provide detections of a different kind. These detections can be represented by a position, shape, or appearance information, such as class. Hence, \(m_{a_i,b_j}\) has to be able to encode all the available similarity information. Let us define \(m_{a_i,b_j}\) in terms of its similarity value as follows:

\[
m_{a_i,b_j}(\{1\}) = \alpha_{i,j}, \quad m_{a_i,b_j}(\{0\}) = \beta_{i,j}, \quad m_{a_i,b_j}(\{1,0\}) = 1 - \alpha_{i,j} - \beta_{i,j},
\]

where \(\alpha_{i,j}\) and \(\beta_{i,j}\) quantify the evidence supporting the singletons in \(\Omega_d\) for the detections \(a_i\) and \(b_j\), i.e., the similarity measures between them.

We can define \(m_{a_i,b_j}\) as the fusion of all possible similarity measures to associate detections \(a_i\) and \(b_j\). Therefore, we can assume that individual masses of evidence carry specific information about these two detections. Let us define \(m_r\) as the evidence measures about the position similarity between detections in \(A\) and \(B\) provided by sources \(S_1\) and \(S_2\) respectively; and \(m^c\) as the evidence measures about the appearance similarity.

Following the analysis made in Section III-A we use Yager’s combination rule defined in Equation 2 to represent \(m_{a_i,b_j}\) in terms of \(m^p_{a_i,b_j}\) and \(m^c_{a_i,b_j}\) as follows:

\[
m_{a_i,b_j}(A) = \sum_{B \in \Gamma \subseteq A} m^p_{a_i,b_j}(B)m^c_{a_i,b_j}(C),
\]

\[
K_{a_i,b_j} = \sum_{B \in \Gamma \subseteq \Omega_d} m^p_{a_i,b_j}(B)m^c_{a_i,b_j}(C), \quad m_{a_i,b_j}(\{\Omega_d\}) = m^p_{a_i,b_j}(\{\Omega_d\}) + K_{a_i,b_j},
\]

where \(m^p_{a_i,b_j}\) and \(m^c_{a_i,b_j}\) represent the evidence about the similarity between detections \(a_i\) and \(b_j\) according to position and class information, respectively.
Once matrix $M_{A,B}$ is built, we can analyse the evidence distribution $m_{a,b,i}$ for each cell to decide if there is an association ($m_{a,b,i}(1)$), there is not($m_{a,b,i}(0)$), or we have not enough evidence to decide ($m_{a,b,i}(1,0)$) which can probably be due to noisy detections. In the next sections we will describe how to calculate these fused evidence distributions using similarity evidence from detections.

When two object detections are associated, the method combines the object representations by fusing the evidence distributions for class information. This fusion is achieved by applying the combination rule described in Equation 2. The fused object representation (kinetic + appearance) is passed as input to the tracking stage to be considered in the objects motion model estimation. Non-associated object detections are passed as well expecting to be deleted by the tracking process if they are false detections or to be verified as real objects in case there is future evidence that confirms it.

It is important to notice that not all the sensors provide the same amount and type of information. For example, while radar data do not include information about the shape of the target, lidar data provide information about the position and the shape of the object. If two associated detections have complementary information, this is passed directly to the fused object representation; if the information is redundant, it is combined according to its type. For the position, we use the Bayesian based fusion presented in [2], which combines the position information of two detections by integrating their covariance matrices. Shape information is usually provided only by the lidar. As stated above, class information is combined using the evidential combination rule from Equation 2.

In the next section we review our proposed methods to extract similarity information from the position and class of the detections. This information is included in Equation 6 to decide if two detections are associated.

1) Position similarity: According to the position of two detections $a_i$ and $b_j$, we encode their similarity evidence in $m_{a,b,i}$. Based on their positions, we can define function $d_{a,b,i}$ as a distance function that satisfies the properties of a pseudo-distance metric. We choose Mahalanobis distance due to its ability to include the correlations of the set of distances. Therefore, a small value of $d_{a,b,i}$ indicates that detections $a_i$ and $b_j$ are part of the same object; and a large value indicates the opposite. All the propositions for $m_{a,b,i}$ belong to the frame of discernment $\Omega_d$. Hence, the BBA for $m_{a,b,i}$ is described as follows:

$$m_{a,b,i}(\{1\}) = a f(d_{a,b,i}), \quad m_{a,b,i}(\{0\}) = a(1 - f(d_{a,b,i})), \quad m_{a,b,i}(1,0) = 1 - a$$

where $a \in [0,1]$ is an evidence discounting factor and $f(d_{a,b,i}) \rightarrow [0,1]$. The smaller the distance, the larger value given by function $f$. In our case we choose $f$ as:

$$f(d_{a,b,i}) = \exp(-\lambda d_{a,b,i}),$$

where $\lambda$ is used as a threshold factor that indicates the border between close and far distances.

2) Class dissimilarity: Contrary to the evidence provided by position, class information does not give direct evidence that supports the proposition $P(a_i, b_j) = 1$. This means that even if two detections are identified with the same class, one can not affirm that they are the same object. This is due to the fact that there can be multiple different objects of the same class in the current driving scenario. However, it is clear that if two detections have different classes it is more likely that they belong to different objects. Hence, we use the class to provide evidence to the dissimilarity between detections: $m_{a,b,i}$. The frame of discernment for the class evidence distribution is the set $\Omega = \{p, b, c, t\}$. The frame of discernment for detections’ association is $\Omega_d$ and was described in Section VIII-A. Hence, we transfer the evidence from in $\Omega$ to $\Omega_d$ as follows:

$$m_{a,b,i}(\{1\}) = 0, \quad m_{a,b,i}(\{0\}) = \sum_{A \cap B = \emptyset} m^c_{a}(A)m^b_{b}(B), \quad \forall A, B \subset \Omega, \quad m^c_{a,b,i}(1,0) = 1 - m_{a,b,i}(\{0\}),$$

which means that we fuse the mass evidences where no common class hypothesis is shared between detections in lists $A$ and $B$. $m^c_{a}$ and $m^b_{b}$ represent the BBAs for the class hypotheses of detections in lists $A$ and $B$. However, as we have no information about the possible relation of detections with the same class, we place the rest of the evidence in the ignorance hypothesis $\{1,0\}$.

B. Moving object tracking

Using the combined list of object detections provided by our fusion approach, we modified the model-based moving object tracking approach described in [1]. We adapted a MCMC sampling process using our composite representation to find the best trajectories of tracks (hypotheses) in a sliding window of time. Generated object hypotheses are then put into a top-down process taking into account all the object dynamics models, sensor model, and visibility constraints. However, instead of searching in all the possible neighbour hypotheses, we use the class evidence distribution of each object detection to reduce the search space by considering the hypotheses with more mass evidence. Two objects have similar classes if their classes belong to the same general set. Two sets of classes are defined as general: $\text{vehicle} = \{c, t\}$ and $\text{person} = \{p, b\}$.

If an object has a high evidence mass in the hypothesis $\{c\}$, we only sample the possible hypotheses for $c$ and $t$. When the highest mass evidence is placed in a non-singleton hypothesis, such as $\text{vehicle}$, the search space is expanded to include $c$ and $t$ samples alike.

We perform a dynamic fusion strategy, as described in [9], to associate the object’s current state delivered by our fusion approach, and the object description of the current track. This allows to keep the object class information up-to-date each time new sensor data is available. Hence, the final output of our DATMO solution is composed of a list of moving objects described by their kinetic information and by a set of all the possible class hypotheses represented by masses of evidence.
IX. EXPERIMENTAL RESULTS

Using the sensor set-up described in Section VI, we gathered four datasets from real scenarios: two datasets from urban areas and two data sets from highways. Both data sets were manually tagged in order to provide a ground truth reference. We analysed the degree of improvement achieved by early inclusion of class information within the DATMO component. Moreover, we performed a comparison between the fusion approach at tracking level described in [9] and our fusion approach at detection level using the same experimental scenarios.

In our DATMO solution at detection level, we first performed SLAM for the lidar sensor measurements (see Section VI-A) to detect the possible moving entities. Among the 2D position state for each detection, we define the frame of discernment \( \Omega = \{ p, b, c, t \} \) for its evidence class distribution. Therefore, \( 2^{| \Omega |} \) is the number of all the possible class hypotheses for each detection. Then, the object representations for lidar, radar and camera detections are extracted following the methodologies presented in Sections VI and VII. Once we obtained the object representations, we perform the fusion at detection level and the tracking of the fused list of objects as detailed in Section VIII.

Fig. 8 shows two output examples of our complete PS in highway and urban areas. Both scenarios are considered as high-traffic scenarios due to the large number of moving objects around the vehicle. In both cases, all vehicles, including oncoming ones, are well detected, tracked and correctly classified: several cars and two trucks in the highway; and several cars, one truck and one pedestrian in the urban area. Additionally, static objects (such as barriers) are also reported and correctly identified as static obstacles using the method described in Section VI-A. In the top view of these examples moving objects velocity is estimated by the model-based tracking module which takes advantage of the composite object representation to deliver speed and orientation. In the early fusion stage, the radar Doppler velocity information helps to improve the target speed estimated by the lidar after its moving direction is known. Also, the class of the object is improved by the fused information from the three different sensors providing a more reliable class hypothesis in the form of a class distribution. The continuous support applications use this class distribution to decide the correct actions.

In the output of our perception approach, a moving object is represented by several pieces of information: location, geometry, object class, speed, and moving direction that cannot be provided by only one individual sensor. The size of the bounding box is updated using the visible lidar measurements, the fixed-size class models and the lateral information from camera classification. The height of a bounding box is set according to the class of the detected object and to the result from camera classifiers.

Tables I and II show a comparison between the results obtained by the proposed fusion approach at detection level and our previous fusion approach at tracking level presented in [9]. It takes into account the erroneous classifications of moving objects. We use four datasets to conduct our experiments: 2 datasets from highways and 2 datasets from urban areas. We can see that the improvement of the fusion at detection level in highways with respect to the tracking level fusion is not considerable. However, in high-speed situations, the certainty about the moving vehicles is quite important. Hence, this small improvement is very useful for the final applications, such as continuous support systems. Urban areas represent a modern challenge for vehicle perception. The improvement of the fusion approach at detection level was considerable compared to our other fusion approach. Here, the richer representation of sensor detections and the data association relations allowed the early detection of real moving vehicles.

Regarding the pedestrian classification results, we obtained similar improvements to those obtained for vehicle detections. The problem of small clusters detected by lidar as moving obstacles but without the certainty of being classified as pedestrians is mainly overcome by the early combination of class information from radar and camera-based classification. Furthermore, the classification of moving objects (not only pedestrians) in our proposed approach takes on average less sensor scans than the compared fusion approach described in [9]. This is due to the early integration of the knowledge about the class of detected objects placed in \( m_b \) and \( m_p \), which is directly related to the reduced search space for the shape and motion model discovering process performed by the MCMC technique.

A. On-line evaluation

Based on the running-time statistics of our PS, in urban areas (the most challenging scenario), the average
computing time is 40ms which fulfils the processing time requirement of the designed real-time platform (75ms).

In rural areas and highways, the processing of the whole PS can be reduced to 30ms.

Table III summarizes the results collected after testing our PS with on-line data in four different scenarios. Correct detections represent true moving objects. False detections represent detections wrongly recognized as moving objects. Correct classifications represent well classified moving objects. False classifications are self-explanatory. For clarity sake, the number of correct and false detections, and classifications are also represented by percentages. Four objects of interest were taken into account: pedestrians, bikes, cars and trucks.

In test track scenarios, where only few cars and pedestrians are present, the detection and classification rate of pedestrians and cars are nearly perfect (96-100%). This scenario does not contain many common driving situations, such as several moving objects and high traffic dynamics. However, it allows us to test specific components of the PS, e.g., pedestrian and vehicle classification, and moving vehicle tracking.

In highways, the detection rate of vehicles is also very good: car (97.8%), truck (96.4%) where the missed detections are due mainly to inherently noisy and cluttered data (e.g., lidar impacts on the ground). The large size of the truck makes the truck detection not as accurate as car detection since it is sometimes confused with the barrier. The false detection rate (2.2%) is due mainly to the reflection in raw lidar data which creates ghost objects and the noisy radar target detection. However, the fusion approach allows the ability to obtain a highly correct classification rate for both cars or trucks whilst keeping a very low false classification rate.

In urban areas, vehicle detection and classification is still high, considering the increased number of moving obstacles and the cluttered environment. However, the false detection rate is higher than in highway scenarios. This increase is due to the highly dynamic environment and to the reduced field of view in high traffic situations. Moreover, the pedestrian false classifications commonly appears when the classifiers mis-classify traffic posts as pedestrians. These mis-classifications suggest the construction of more robust visual classifiers or the implementation of more discriminating visual descriptors.

In Rural roads, several moving objects of interest may appear, but high traffic dynamics are not present. Besides, there are less traffic landmarks. The false-classification rates obtained in this scenario are higher than the ones obtained from the other three scenarios. This is due to the increasing number of natural obstacles, such as bushes and trees. The common object false classifications are due to false moving objects (mainly bushes) preliminary classified as trucks or pedestrians. One solution could be to implement a dedicated classifier to discard this type of obstacles.

X. Conclusions and Perspectives

In this paper we have reviewed the problem of intelligent vehicle perception. Specifically, we have focus on the DATMO component of the perception task. We have proposed the use of classification information as a key element of a composite object representation, where not only kinetic information but appearance information plays an important role in the detection, classification and tracking of moving objects of interest. We have analysed the impact of our composite object description by performing multi-sensor fusion at detection level. We used three main sensors to define, develop, test and evaluate our fusion approach: lidar, radar, and camera. Moreover, our complete perception solution was evalu-
