Abstract

A new functional-structural model SUNLAB for the crop sunflower (*Helianthus annuus* L.) was developed. It is dedicated to simulate the sunflower organogenesis, morphogenesis, biomass accumulation and biomass partitioning to organs. It is adapted to model phenotypic responses of different genotypic variants to diverse environmental factors including temperature stress and water deficit. A sensitivity analysis was conducted to quantify the relative parameter influences on the main trait of interest, the grain yield. The model was calibrated for four genotypes on two experimental datasets collected on plants grown under standard non-limiting conditions and moderate water stress. Its predictive ability was then tested on an additional dataset. The four considered genotypes - “Albena”, “Melody”, “Heliasol” and “Prodisol” - are the products of more than 30 years of breeding effort. Comparing the values found for the four parameter sets associated to each variant, allows to identify genotype-specific parameters. The model also provides a novel way of investigating genotype performances under different environmental conditions. These promising results are a first step towards

the potential use of the model as a support tool to design sunflower ideotypes adapted to the current worldwide ecological and economical challenges and to assist the breeding procedure.

9 *Keywords:* SUNLAB, SUNFLO, GREENLAB, Sunflower model

10 **1. Introduction**

11 As one of the major oilseed crops worldwide, sunflower production has
12 to face the growing social demand in a context of strong ecological and eco-
13 nomical constraints: growers are confronted to the challenge of increasing
14 sunflower productivity under changing climatic conditions while maintaining
15 low input levels and reduced costs. A partial response to this challenge could
16 be found by breeding new genotypes or by identifying the best genotype,
17 among a set of existing ones, for a given location and for given management
18 practices; see for instance Allinne et al. (2009).

19 Assessments of genotype performances for *in situ* experimental trials ham-
20 per the breeding process by temporal, logistic and economical difficulties.
21 Indeed, genotypes perform differently depending on the environmental con-
22 ditions (soil, climate, etc.) and the management practices (sowing date,
23 nitrogen inputs, irrigation, etc.). Therefore a large number of trials are
24 needed to explore a sufficiently diverse set of genotypes x environment x
25 management (GxExM) combinations in order to characterize these complex
26 interactions. An emerging approach to overcome these difficulties relies on
27 the use of models represented as a set of biophysical functions that deter-
28 mine the plant phenotype in response to environmental inputs. Models can
29 help in breeding strategies and management by dissecting physiological traits

30 into their constitutive components and thus allow shifting from highly inte-
31 grated traits to more gene-related traits that should reveal more stable under
32 varying environmental conditions (Yin et al., 2004; Hammer et al., 2006).

33 Consequently, an important question to examine is how to design models
34 that can be used in that context. The models should simulate the phenotypic
35 traits of interest (e.g. yield) with good robustness and predictive capacity.
36 The models should also present a trade-off between mechanistic aspect and
37 complexity: Chapman et al. (2003) state that, for such use, a growth model
38 should include ‘principles of response and feedbacks’ to ‘handle perturbations
39 to any process and self-correct, as do plants under hormonal control when
40 growing in the field’ and to ‘express complex behavior even given simple op-
41 erational rules at a functional crop physiological level’. Casadebaig et al.
42 (2011) discuss that question in the case of their model SUNFLO (Lecoeur
43 et al., 2011). SUNFLO is a biophysical plant model that describes organo-
44 genesis, morphogenesis, and metabolism of sunflower (*Helianthus annuus L.*).
45 It has shown good performances to identify, quantify, and model phenotypic
46 variability of sunflower at the individual level in response to the main abi-
47 otic stresses occurring at field level but also in the expression of genotypic
48 variability (Casadebaig et al., 2011). The authors mixed mechanistic and sta-
49 tistical approaches to deal with highly integrative variables such as harvest
50 index (HI). This HI factor is determined by a simple statistical relation-
51 ship dependent on covariables previously simulated by the mechanistic part
52 of the crop model throughout the growing season. Although this statistical
53 solution and the large datasets used for its parameterization conferred good
54 robustness to the prediction of HI and thereby crop harvest, biomass parti-

tioning to other plant organs and trophic competition between organs were
 not taken into account. Fenni: Here, in last review, the third reviewer posed
 a question “ The idea of formalizing trophic competition between organs (p 4
 l 27-33) is at the core of this new model. You write that such a formalization
 should help representing feedback effects of biomass partitioning on “other
 processes” (p 4 l 13-15). What do you mean?”, I simply deleted the sentence
 that saying “feedback effects of biomass partitioning on other processes can-
 not be taken into account”, but I still tried to mention it in the discussion
 saying “The plants are considered only at the minimal level of organ com-
 partments. PBM model ignores plant architecture and its plasticity. The
 lack of individual organ’s simulation can influence the simulation of plant
 functioning. For example, PBMs models normally use the relative values of
 the sink strength of organs to simulate biomass partitioning. These sink val-
 ues are assessed directly from experiments and the sources and sinks have no
 significant direct interaction in these models (de Reffye et al., 2008). How-
 ever, the lack of trophic competition simulation may hinder the simulation of
 feedback effects of biomass partitioning on other processes. As Pallas et al.
 (2008) state, trophic competition influenced the organogenesis of grapevine
 in their research”. That paragraph had been deleted by you in last revision.
 Do you think we should still mention somewhere this idea “mechanistic sink-
 source solver helps the simulation of biomass partitioning, and also the future
 possibility of simulating feedback effects”?. I added one sentence in the dis-
 cussion to add about considering feedback effects:”Introducing a mechanism
 of trophic competition at organ level in a PBM, as done in this study, opens
 the possibility to model feedbacks effects of biomass partitioning on other

80 processes such as photosynthesis or organogenesis (Mathieu et al., 2009).
 81 ”‘. Do you agree? Moreover, it was shown in Lecoecur et al. (2011) that
 82 *HI* is the parameter that contributes the most (14.3%) to the coefficient of
 83 variation of the potential grain yield. It was also shown that when ranking
 84 the processes in terms of their impact on yield variability, the first one was
 85 biomass allocation (before light interception according to plant architecture,
 86 plant phenology and photosynthesis). Therefore, Lecoecur et al. (2011) sug-
 87 gested that a better formalisation of the trophic competition between organs
 88 could be a way to improve our understanding of genotypic variation for the
 89 harvest index Fenni: here the third reviewer posed another question last
 90 time “ Please elaborate and give appropriate references to clarify the idea of
 91 formalizing trophic competition (direct formalization? It could also be indi-
 92 rect) and to construct a sound argument (e.g. which outlines to satisfy the
 93 need of feedback effects of biomass partitioning).” I actually didn’t answer
 94 his question about direct formalization or indirectIn fact I don’t understand
 95 the reviewer’s question; what do you think he means by ”‘direct or indi-
 96 rect formalization”’?. In order to take up this challenge, a new sunflower
 97 model, named SUNLAB, was derived from SUNFLO. The representation
 98 of plant topological development and allocation process at individual organ
 99 scale were inspired by the functional-structural plant model GREENLAB,
 100 which has been designed as a “source-sink solver” (Christophe et al., 2008)
 101 and which is accompanied with the appropriate mathematical tools for its
 102 identification (Cournede et al., 2011). SUNLAB thus inherits from GREEN-
 103 LAB the flexible rules of sink competition for biomass partitioning at organ
 104 scale Fenni:the deleted phrases “(organ type includes blade, petiole, intern-

ode and capitulum; a leaf consists of a blade and a petiole; for the modeling of trophic competition, blade and petiole are considered as two organ types)” were actually trying to answer the second reviewer’s question in the previous review “ you are using the word “blade” to designate the leaves all over the manuscript. This is somewhere confusing. The manuscript would benefit to clarify this”. Maybe somewhere a small explanation of blade could be added if it is deleted here Yes, I had taken care of that and I had added it in the MM part, in *plantstructure* paragraph as ”‘ The different organ types, denoted as o, include leaves (decomposed into blades and petioles),”’ Do you think that it will be ok ?, together with the more detailed representation of ecophysiological processes and environmental stress effects on biomass production and yield from SUNFLO.

This paper presents in detail the mechanisms of SUNLAB and the parameter estimation procedure based on field experimental data. A sensitivity analysis is performed on the model parameters, using the Sobol method, to investigate the relative contribution of each parameter and their interactions to the model output uncertainty. The output that we consider is the main trait of interest in most breeding procedures, that is the final grain yield. The potentials of SUNLAB for genotypic characterization are illustrated by comparing the parameters obtained after the estimation process for four genotypes, namely “Albena”, “Heliasol”, “Melody” and “Prodisol”. The performances of SUNLAB to reproduce phenotypic variability coming either from genotypic or from environmental influences are tested against experimental datasets used for parameterization. An additional dataset is then used for model evaluation. An interesting and uncommon output of

SUNLAB is the simulation of specific leaf area (SLA, also known as leaf specific surface area, $cm^2.g^{-1}$), *i.e.* the ratio of leaf area to dry leaf mass. It is an influent input variable often associated with large uncertainty ranges in most dynamic crop growth models (Rawson et al., 1987).

2. Materials and methods

2.1. Modeling: SUNLAB modules

SUNLAB consists of five modules: phenology, water budget, organogenesis and morphogenesis, biomass accumulation, and biomass partitioning. Phenology, water budget, and biomass accumulation modules are directly inherited from the SUNFLO model. The organogenesis and morphogenesis module is modified from the corresponding SUNFLO module by defining for each organ the dates, expressed in thermal time, of initialization, termination of its growth, and organ expansion. The biomass partitioning module is an entirely new module. We describe here equations of these modules, briefly for those inherited from SUNFLO - we refer to Casadebaig et al. (2011) and Lecoeur et al. (2011) for an exhaustive description - and in detail for the new contributions. Model parameters that are mentioned in the following equations will be summarized in section 2.3.

2.1.1. Phenology

Plant phenology is driven by thermal time. Cumulative thermal time on day d since emergence, $CTT(d)$ ($^{\circ}C\ days$), is calculated in equation (1) as the sum of the daily mean air temperature $T_m(d)$ ($^{\circ}C$) above a base temperature T_b of $4.8\ ^{\circ}C$, common to all sunflower genotypes. Four key phenological stages, expressed as genotype-dependent thermal dates ($^{\circ}C\ days$),

are defined: flower bud appearance $E1$, beginning of flowering $F1$, beginning of grain filling $M0$ (early maturation) and physiological maturity $M3$ (Lecoeur et al., 2011). Crop development can be accelerated by water stress, that causes overheating of the plant through the reduction of transpiration. This is modeled by using a multiplicative effect of water stress at day d , $FHTR(d)$ (the effect of water on transpiration), on thermal time accumulation $CTT(d)$:

$$T_{eff}(d) = \max(0, (T_m(d) - T_b))$$

$$CTT(d) = \sum_{k=1}^d T_{eff}(k) \times [1 + 0.1 \times (1 - FHTR(k))] \quad (1)$$

where $T_{eff}(k)$ is the effective thermal time at day k . $FHTR(d)$ is calculated as a function of the fraction of transpirable soil water at day d , $FTSW(d)$ (detailed in 2.1.2), divided by a genotypic parameter RT of sensitivity to water deficiency (Casadebaig et al. (2011)).

2.1.2. Water budget

In SUNLAB, the water cycle of sunflower is modeled considering the plant processes (root water absorption and transpiration), in combination with its direct environment: precipitation, irrigation, soil evaporation (see Fig. 1a). Evaporation and plant transpiration decrease the available amount of water in soil, while irrigation and precipitation refill it.

[Figure 1 about here.]

The index for the assessment of drought level $FTSW(d)$ at day d depends on the simulation of the above mentioned processes (Lecoeur et al., 2011). It takes values from 0 (no water stress) to 1 (severe water stress) and it is

175 used to define three indices to tune three plant functioning processes: leaf
 176 expansion $FHLE$, radiation use efficiency $FHRUE$ and plant transpiration
 177 $FHTR$. The critical thresholds RT and RO are genotype-dependent pa-
 178 rameters varying in $[0, 1]$ that characterize the plant drought tolerance (RT ,
 179 drought tolerance of leaf expansion; RO , drought tolerance of radiation use
 180 efficiency and transpiration). For instance, $FHRUE$ is calculated as:

$$FHRUE(d) = \begin{cases} FTSW(d)/RT & \text{for } FTSW(d) < RT \\ 1 & \text{for } FTSW(d) \geq RT \end{cases} \quad (2)$$

181 Its effect on radiation use efficiency $RUE(d)$ ($g.MJ^{-1}$) is defined as:

$$RUE(d) = RUE_p(d) \times \min\left(1, \frac{FTSW(d)}{RT}\right) \times FT(d) \times PHS \quad (3)$$

182 where $RUE_p(d)$ ($g.MJ^{-1}$) is the crop potential (maximal) radiation use ef-
 183 ficiency, $FT(d)$ is the thermal stress on day d , a function of daily mean
 184 temperature (Lecoeur et al., 2011) and PHS is a genotypic parameter giving
 185 the ratio of the genotype photosynthesis capacity to that of the reference
 186 genotype “Melody”. The potential radiation use efficiency is thus weakened
 187 by the environmental thermal stress factor $FT(d)$ and the drought stress
 188 factor $FHRUE(d)$.

189 2.1.3. Organogenesis and morphogenesis

190 *Ecophysiological functions.* The number of blades $N(d)$ on day d increases
 191 linearly with cumulative thermal time $CTT(d)$:

$$N(d) = R \times CTT(d) + 1 \quad (4)$$

192 where R (leaves/ (°C days)) is the rate of leaf production. Leaf senescence
 193 occurs during the period of grain filling between M0 and M3. Consequently

194 the number of senescent leaves $NS(d)$ is considered to increase in proportion
 195 to the time elapsed since $M0$ (Sinclair and de Wit, 1975; Nooden et al., 1997)
 196 as:

$$NS(d) = N_{total} \times \frac{M3 - CTT(d)}{M3 - M0} \quad (5)$$

197 where N_{total} is a genotypic parameter equal to the maximal number of leaves.
 198 Since, in sunflower, leaf area distribution along the stem shows a bell shape,
 199 total leaf area $A(d)$ (cm^2) per plant is calculated with a logistic equation:

$$A(d) = \frac{A1}{1 + e^{4 \times A3 \times (A2 - N(d)) / A1}} \quad (6)$$

200 where $A1$ (cm^2) is the maximal leaf area, $A2$ and $A3$ (cm^2) are respectively
 201 the rank and the area of the largest leaf of the plant. The calculation of
 202 senescent leaf area $AS(d)$ (cm^2) is determined by a similar logistic equation
 203 but replacing $N(d)$ by $NS(d)$. The photosynthetically active leaf area $AA(d)$
 204 (cm^2) is estimated as the difference between total leaf area $A(d)$ and senescent
 205 leaf area $AS(d)$. Leaf growth and senescence are affected by water stress and
 206 temperature stress coefficients as described in Casadebaig et al. (2011).

$$AA(d) = \frac{A1}{1 + e^{4 \times A3 \times (A2 - N(d)) / A1}} - \frac{A1}{1 + e^{4 \times A3 \times (A2 - NS(d)) / A1}} \quad (7)$$

207 *Plant structure.* The different organ types, denoted as o , include leaves (de-
 208 composed into blades and petioles), internodes and capitulum. For each
 209 individual organ o at rank i (i takes its values from 0 to the total amount of
 210 individual organs of type o), its emergence thermal time $initTT(o, i)$, senes-
 211 cence thermal time $seneTT(o, i)$, and growth expansion duration in thermal
 212 time $epdTT(o, i)$ are defined. The thermal time of blade emergence and

senescence are calculated through inversion of equations 4 and 5:

$$\begin{aligned} initTT(blade, i) &= (i - 1)/R \\ seneTT(blade, i) &= M3 - \frac{i \times (M3 - M1)}{N_{total}} \end{aligned} \quad (8)$$

For the calculation of blade expansion duration $epdTT(blade, i)$, three parameters $initTTAdjust$ ($^{\circ}\text{C days}$), $epdTTA$ ($^{\circ}\text{C days}$), $epdTtB$ ($^{\circ}\text{C days}$) are added to the module to calculate $epdTT(blade, i)$ based on the blade emergence and senescence thermal times:

$$\begin{aligned} epdTT(blade, i) &= seneTT(blade, i) - (epdTtB - epdTtA \times i) \\ &\quad - (initTT(blade, i) - initTTAdjust) \end{aligned} \quad (9)$$

Since leaf emergence was recorded when lengths of their central vein are bigger than 4cm (Lecoeur et al., 2011), the leaf has already received a small amount of biomass at the recorded thermal time $initTT(blade, i)$. Therefore, thermal time of blade growth initialization is calculated by subtracting $initTTAdjust$ to the emergence thermal time $initTT(blade, i)$. The thermal times of end of blade expansion linearly vary with their ranks and depend on two parameters, $epdTtA$ and $epdTtB$.

The petiole at rank i shares the same initial, senescence and expansion thermal times as the blade i belonging to the same metamer. The internode i has also the same emergence thermal time as the blade i while its expansion duration $epdTT(internode, i)$ is driven by a parameter $internodeEpdTT$ that is common to all internodes. Capitulum initialization thermal time corresponds to $M0$. Its expansion duration is defined by the parameter $capitulumEpdTT$. These additional parameters to the module are estimated as described in 2.3.

233 With all the information of emergence and senescence thermal times of ev-
 234 ery organ, a general sunflower structure can be constructed. Their expansion
 235 durations are important variables for the calculation of biomass distribution
 236 to organs as presented in 2.1.5.

237 2.1.4. *Biomass accumulation*

238 Daily increase in above-ground dry matter $DM(d)$ ($g.m^{-2}$) is calculated
 239 from Monteith's equation (1977) linking dry matter production to incom-
 240 ing photosynthetically active radiation through two radiation efficiencies as
 241 follows:

$$DM(d) = RUE(d) \times RIE(d) \times PAR_0(d) \quad (10)$$

242 where $PAR_0(d)$ ($MJ.m^{-2}$) is the daily incident photosynthetically active
 243 radiation. $RUE(d)$ ($g.MJ^{-1}$) is daily radiation use efficiency and $RIE(d)$
 244 is daily radiation interception efficiency, estimated from Beer's law. The
 245 total above-ground biomass $CDM(d)$ ($g.m^{-2}$) is the cumulated daily biomass
 246 production from emergence:

$$CDM(d) = \sum_{k=1}^d DM(k) \quad (11)$$

247 2.1.5. *Biomass partitioning*

248 As in GREENLAB, the biomass produced by leaves is distributed to
 249 all organs proportionally to their respective demands. Indeed, it has been
 250 observed for several crops that the final balance of the source and sink rela-
 251 tionships in the end is similar to the action of a common pool of biomass (e.g.
 252 Heuvelink (1995) for tomato): this simplification enables skipping the details
 253 of the transport resistance system and other complex features of branching

254 systems (Christophe et al., 2008). The biomass is dynamically distributed to
 255 every “sink” organ, including blades, petioles, internodes and the capitulum,
 256 regardless of their position within the plant structure. Blades are “sources”
 257 whose photosynthetic production fills the pool biomass. The calculation of
 258 the daily incremental mass of each organ is done through three steps.

259 *First step: Definition of individual organ sink.* Biomass is partitioned to
 260 organs according to their number, age and relative sink strength. The relative
 261 sink strength of organs of given type o is denoted as $SR(o)$, which is a
 262 dimensionless variable indicating the ability of different kinds of organs in
 263 competing for biomass. The relative sink strength of all blades is set to 1 as
 264 a reference value, i.e. $SR(blade) = 1$ (Kang et al., 2008). The growth rate
 265 of an individual organ can vary through its expansion period. This change
 266 is modeled by a normalized discrete Beta density function in GREENLAB
 267 model (Kang et al., 2008) and in this model. Among any empirical functions
 268 that could be suitable, the Beta function is recommended by Yin et al. (2003)
 269 as it presents several advantages: at initial and final times, its values are zero,
 270 it has a high flexibility and can describe asymmetric growth trajectories and
 271 it has stable parameters for statistical estimation. Therefore, the actual sink
 272 strength of an organ $SAP(d, o, i)$ (e.g. the actual sink strength an organ of
 273 type $o = blade$, at rank $i = 2$, on day d $SAP(d, blade, 2)$) can be expressed
 274 as:

$$\begin{aligned}
 SAP(d, o, i) &= \left(1 - \frac{CTT(d) + initTT(o, i)}{epdTT(o, i)}\right)^{sinkB(o)-1} \\
 &\times \left(\frac{CTT(d) - initTT(o, i)}{epdTT(o, i)}\right)^{sinkA(o)-1} \times \frac{SR(o)}{M(sinkA(o), sinkB(o))}
 \end{aligned} \tag{12}$$

275 where $M(A, B)$ is a normalization factor defined as:

$$M(A, B) = \left(\frac{A-1}{A+B-2}\right)^{A-1} \times \left(1 - \frac{A-1}{A+B-2}\right)^{B-1} \quad (13)$$

276 Two organ-type-specific parameters $sinkA(o)$ and $sinkB(o)$ control the
 277 function shape, as illustrated in the result section Fig.4. Thus, the sink
 278 activity of an organ o at rank i starts from $initTT(o, i)$ and lasts during the
 279 organ's expansion duration $epdTT(o, i)$.

280 *Second step: Total demand.* The plant total demand $sumSink(d)$ is com-
 281 puted as the scalar product of the number of existing organs by their sink
 282 strength $SAP(d, o, i)$:

$$sumSink(d) = \sum_t \sum_i SAP(d, o, i) \quad (14)$$

283 *Third step: biomass partitioning to organs.* The total dry biomass $CDM(d)$
 284 that is produced at day d is allocated to every individual organs propor-
 285 tionally the ratio of their sink strength $SAP(d, o, i)$ to the total plant de-
 286 mand $sumSink(d)$. For example the biomass allocated to an individual blade
 287 $indMS(d, blade, i)$ ($g.m^{-2}$) of blade ranking i is:

$$indMS(d, blade, i) = \frac{CDM(d) \times SAP(d, blade, i)}{sumSink(d)} \quad (15)$$

288 Total blade biomass $organMS(d, blade)$ ($g.m^{-2}$) at time d is the sum of all
 289 individual blade biomass:

$$organMS(d, blade) = \sum_i indMS(d, blade, i) \quad (16)$$

290 Similarly, individual and total petiole biomass ($indMS(d, petiole, i)$ and $organMS(d, petiole)$,
 291 $g.m^{-2}$) are simulated, as well as individual and total internode biomass
 292 ($indMS(d, internode, i)$ and $organMS(d, internode)$, $g.m^{-2}$), and capitu-
 293 lum biomass ($indMS(d, capitulum, i)$ and $organMS(d, capitulum)$, $g.m^{-2}$).

2.2. Field experiments and measurements

Experiments and measurements for designing and constructing modules which are directly inherited from SUNFLO are not presented in this paper, as they are described in detail in Lecoeur et al. (2011). Data used for SUNLAB parameters estimation, simulation and application include three datasets, respectively entitled as “2001”, “2002a” and “2002b”. They all come from field experiments conducted in 2001 and 2002 at SupAgro experimental station at Lavalette (43° 36’N, 3° 53’ E, altitude 50 *m*) on a sandy loam soil for four genotypes “Albena”, “Heliasol”, “Melody” and “Prodisol”. In “2001”, Sunflowers were sown on 5 May 2001 at a density of about 6 plants m^{-2} and a row spacing of 0.6 m, in a randomized complete block design with four replications. Plots measured 5.5. $\times$ 13.0 *m*. In the other two datasets, experiments were conducted with the same plant arrangement. But sunflowers were sown on 15 May 2002 and plots measured 8.0 $\times$ 8.0 *m*. During the experiment, meteorological data such as temperatures and radiation were recorded. The total amount of water available for the plant was calculated as the difference between soil water content at field capacity estimated at the beginning of the experiment and soil water content at 10% of maximal stomatal conductance. The fraction of transpirable soil water (*FTSW*) remaining in the soil at a given date was calculated as the ratio of actual plant-available soil water content to the total plant-available soil water content (Lebon et al., 2006). Organogenesis was described based on the phenomenological stages that were recorded every 2-3 days (Lecoeur et al., 2011). Once a week, six plants per genotype were harvested. Individual leaf areas were estimated from blade lengths and widths. All the above-ground organs (blades, peti-

319 oles, stem, capitulum and seeds) were collected and then oven-dried at 80°C
 320 for 48 h. The dry weights of these organs were measured by compartments.
 321 Daily radiation interception efficiency $RIE(d)$ and daily radiation use ef-
 322 ficiency $RUE(d)$ were respectively calculated and estimated based on field
 323 measurements as in (Lecoeur et al., 2011). In all experiments, the crop was
 324 regularly irrigated and fertilized to avoid severe water deficits and mineral
 325 deficiency. But in practice, the three experiments showed different water
 326 deficit conditions. The index $FTSW$ of the three experiments, which can
 327 represent the water stress level, is illustrated (Fig.2). Since the experiment
 328 measurements were carried out every a few days, an interpolation on exper-
 329 imental data was drawn to make the contrast clearer. Datasets “2001” and
 330 “2002a” correspond to contrasted environmental conditions and are used to
 331 calibrate SUNLAB model while “2002b” is used for model evaluation.

332 [Figure 2 about here.]

333 2.3. Parameter analysis

334 Four genotypes “Albena”, “Melody”, “Heliasol” and “Prodisol” are con-
 335 sidered in this paper. These genotypes have been characterized by a large
 336 study of genetic improvement of sunflower over the last 30 years, and they
 337 are four of those most widely grown varieties in France from 1960 to 2000
 338 (Vear et al., 2003). SUNLAB parameters can be decomposed in two subsets.
 339 One subset contains the parameters inherited from SUNFLO which keep the
 340 same values in SUNLAB (Table 1).

341 [Table 1 about here.]

342 The other subset contains 17 additional parameters, that are introduced in
 343 SUNLAB, as was presented in section 2.1. They include 12 parameters that
 344 drive the sink competition (SR , $sinkA$, $sinkB$ for four types of organs) and 5
 345 parameters, that are used to adjust or define initial and final organ expansion
 346 thermal times: $initTTAdjust$ ($^{\circ}C\ days$), $epdTTA$ ($^{\circ}C\ days$), $epdTTB$ ($^{\circ}C$
 347 $days$), $internodeEpdTT$ ($^{\circ}C\ days$), and $capitulumEpdTT$ ($^{\circ}C\ days$). Note
 348 that the sink strength of blades $SR(blade)$ is set to 1 as a reference value
 349 (Christophe et al., 2008), therefore only 16 parameters are included in the
 350 sensitivity analysis and estimation procedure.

351 The non-linear generalized least squares method with Gauss Newton al-
 352 gorithm for optimization (Cournede et al., 2011) was used for estimating the
 353 16 parameters of four genotypes. The target field data include (i) total blade
 354 mass, total petiole mass, total internode mass, and capitulum mass, all col-
 355 lected once a week during 15 weeks in total, and (ii) individual blade mass.
 356 Regarding the target field data at organ scale used for parameter estimation,
 357 only individual blade area data was available. All organs were only weighted
 358 at compartment scale. In particular, independent blade mass data was not
 359 available, while these data are required for a better estimation of SUNLAB
 360 parameters. Therefore, profiles of individual blade mass were estimated as
 361 follows: at each date when total blade mass and total blade areas were mea-
 362 sured at compartment level, a virtual SLA value was computed as the ratio
 363 of these two quantities and was used to generate a set of individual blade
 364 mass from the sequence of areas. The model can thus be viewed as a dynamic
 365 interpolation solver that generates both blade areas and mass between those
 366 fixed measurement dates. Since these measurements at individual scale were

367 performed 6 times, the estimated blade mass represent around 150 data for
 368 each genotype, to be added to the 60 data at compartment scales, giving a
 369 total of around 210 observation data used for the parameter estimation of
 370 each genotype.

371 A sensitivity analysis was performed on SUNLAB parameters to under-
 372 stand their relative influence on determining the main model output, the
 373 yield Y . A global method was used, the Sobol method (Saltelli et al., 2000;
 374 Wu and Cournede, 2010). In this method, parameters are considered as
 375 random variables that are drawn from predefined distributions, chosen here
 376 as uniform distributions since no *a priori* knowledge is available for the 16
 377 SUNLAB parameters. Plausible interval boundaries are defined: the lower
 378 boundary is set as 0.5 times of the parameter's minimum estimated value
 379 among all genotypes, and the upper boundary is set as 1.5 times of the pa-
 380 rameter's maximum estimated value. This allows computing an estimator
 381 of the output variance, $V(Y)$. The first-order sensitivity index of a given
 382 parameter X_i can thus be defined as:

$$S_i = \frac{V_{X_i}(E_{\sim X_i}(Y|X_i))}{V(Y)} \quad (17)$$

383 where the inner expectation operator is the mean of Y taken over the possible
 384 values of all other parameters except X_i ($E_{\sim X_i}$) while keeping X_i fixed. Then
 385 outer variance is taken over all possible values of X_i . Similarly, higher order
 386 sensitivity indices can be defined to characterize the effects of interactions
 387 between parameters on the output variance. Sensitivity indices are normal-
 388 ized thanks to the well-known formula of variance decomposition. Here, 1000
 389 parameter sets are generated from the Sobol sequence in the calculation.

390 This crop model SUNLAB and the statistical analysis methods are inte-
 391 grated in the platform PYGMALION (Cournède et al., 2013): this platform
 392 is currently developed and used in the laboratory of Applied Mathematics
 393 and Systems at Ecole Centrale Paris, and is available to a few other labs for
 394 collaborative research projects. Programmed in C++ computer language, it
 395 is dedicated to the mathematical analysis of plant growth models, including
 396 the parameter estimation and sensitivity analysis methods used in this pa-
 397 per. It comprises approximately 20 classical and new models of plant growth,
 398 among which are Greenlab (Hu et al., 2003), PILOTE (Mailhol et al., 1997,
 399 2004), STICS (Brisson et al., 1998), SUNFLO (Casadebaig et al., 2011) and
 400 SUNLAB.

401 **3. Results**

402 *3.1. Sensitivity analysis*

403 A sensitivity analysis was performed on the 16 parameters (described in
 404 2.3) of SUNLAB for the yield, using the Sobol method of variance decompo-
 405 sition. Results are gathered in Table 2 for the most influential parameters.
 406 The sum of all first order indices was 0.87, which means that the part of
 407 variance due to parameter interactions was less than 15%: this justifies that
 408 the sensitivity analysis of this model can be grounded on first-order indices
 409 of parameters. The most influential parameters are those driving the dynam-
 410 ics of capitulum sink variations, $sinkA(cap)$ and $sinkB(cap)$, accounting for
 411 51% and 12% respectively of the yield variance. The only other parameter
 412 with significant sensibility index is a parameter of internode sink variation,
 413 $sinkA(intern)$. All other parameters account for less than 5% of the yield

414 variance. This result suggests that dynamics of biomass allocation to the
415 capitulum, more than the value of its sink, are important for yield determi-
416 nation.

417 [Table 2 about here.]

418 3.2. Model parameterization

419 3.2.1. Parameter estimation for four sunflower genotypes

420 The SUNLAB parameters were estimated for the four different geno-
421 types (“Albena”, “Melody”, “Heliasol”, and “Prodisol”) using experimental
422 datasets of “2001” (non-limiting conditions) and “2002a” (with water deficit).
423 The values of the 12 sink competition related parameters are shown in Table
424 3 with the associated standard deviation.

425 These parameter values were independently estimated for each genotype,
426 *i.e.* no *a priori* genotypic correlations were imposed. This allows comparing
427 the genotypes according to their parameter values. The standard error could
428 allow testing the significance of differences between two parameter values, but
429 this would only be an approximate result since the number of observations
430 that directly influence the estimation of each parameter was unknown. **to**
431 **change with the results of the test.** Qualitative observations can nevertheless
432 be done. For example, blade parameter $sinkA(blade)$ in the sink variation
433 function of blades appears significantly different between four genotypes,
434 while no clear evidence of genotypic variability was found for capitulum sink
435 strength ratio $SR(capitulum)$ (see also Fig. 4). The internode sink ratio,
436 $SR(internode)$, was found different for genotypes “Albena” and “Melody”,
437 but took similar values for “Heliasol” and “Prodisol”.

438

[Table 3 about here.]

439 *3.2.2. Model performances: reproducing genotype-induced variability*

440 Even when grown under non-limiting controlled conditions, the four stud-
 441 ied varieties presented some phenotypic variability, that might be intrinsically
 442 regulated by genotypic influences. This phenotypic variability was in partic-
 443 ular observed on daily radiation interception efficiency $RIE(d)$, total blade
 444 area $AA(d)$, leaf number $N(d)$, cumulated dry biomass $CDM(d)$ and biomass
 445 partitioning. This is illustrated in Fig. 3 for dry mass compartments (blade,
 446 internode and capitulum) with the “2001” experimental dataset. This figure
 447 also illustrates the model ability to reproduce this (presumably) genotypic
 448 variability.

449

[Figure 3 about here.]

450 The estimated parameter values (Table 3) allow tracking back the dy-
 451 namics of biomass allocation and analyzing the internal mechanisms under-
 452 lying sink competition. For instance, compared to “Prodisol”, blades of
 453 “Albena” entered earlier in the competition for biomass but the capitulum
 454 reached its maximum demand later (Fig. 4): this may explain that in the
 455 end “Albena” had bigger total blade biomass but smaller capitulum biomass
 456 than “Prodisol” (Fig. 3). Genotypic characterization can also come from the
 457 biomass accumulation module: “Melody” had larger internode and capitu-
 458 lum biomass than “Heliasol”, and they had similar blade biomass, as can
 459 be seen in Fig. 3. This was due to a higher radiation use efficiency of the
 460 “Melody” genotype.

461

[Figure 4 about here.]

462 *3.2.3. Model performances: reproducing environment-induced variability*

463 The SUNLAB model was calibrated using “2001” and “2002a” exper-
464 imental datasets that included data for plants grown without water deficit
465 (“2001”) and plants grown under water deficit (“2002a”). The parameterized
466 SUNLAB model was able to simulate the phenotypic variability induced by
467 the two contrasted environmental conditions of “2001” and “2002a” datasets.
468 This is illustrated in Fig.5 that shows experimental data and simulations of
469 radiation interception efficiency $RIE(d)$, total blade area $AA(d)$, leaf number
470 $N(d)$, cumulated dry above-ground biomass $CDM(d)$ and biomass compart-
471 ments (capitulum, blades, petioles, internodes) for the “Melody” genotype.
472 It can be noticed that “Melody” was not very sensitive to water stress since
473 the dry mass accumulation did not significantly vary. Graph B shows that
474 there were under-estimations of total blade area. This was due to the mod-
475 eling equations of leaf area (see equation 6 and equation 7). These equations
476 are inherited from SUNFLO model and define a common formula for all geno-
477 types to calculate total leaf area based on genotype-specific parameters $A2$
478 and $A3$. This common formula does not allow to account for all the genotypic
479 variance of total leaf area: possible improvements on this part of the model
480 are discussed in section 4. Graph E and Graph F of this Fig.5 present some
481 details on two other genotypes: biomass compartments of “Prodisol” and in-
482 dividual blade mass profile for “Heliasol”. Water stress induced a decrease in
483 the capitulum biomass of “Prodisol” plants, despite a slight increase in blade
484 biomass. The effect of water stress can also be observed on the individual
485 blade mass profile of “Heliasol” plants: blades on the last ranks grew less in
486 water deficit conditions (“2002a”) than in standard conditions (“2001”).

[Figure 5 about here.]

3.3. Model evaluation

In order to test the model predictive ability, SUNLAB was confronted to an additional experimental dataset “2002b”, that was not used for the parameterization step. Fig.6 presents some phenotypic traits for the “Albena” genotype: for total blade areas and radiation interception efficiency, data were underestimated by model predictions, total dry biomass was also proportionally affected, but the results were reasonable for the biomass compartment dynamics. The root mean square error (RMSE) of organ mass for genotype “Albena”, calculated on days with available experimental data, was 36.4 and its coefficient of determination was 0.95. However, it has to be noticed that this evaluation process was still at a preliminary step since our additional experimental dataset “2002b” was measured in experimental conditions similar to those of the “2002a” dataset which was used to calibrate the model.

[Figure 6 about here.]

3.4. Model Application: an exploratory study on specific leaf area

Specific leaf area (SLA) is an important variable in plant growth modeling. In most dynamic models, it is usually used to determine blade surface area values from blade biomass, as in GREENLAB (Christophe et al., 2008) or in TOMSIM (Heuvelink, 1999). Since blade area in turn determines the biomass production, accurate estimation of SLA is mentioned as a major source of error in models and implies difficulties in obtaining a reliable computation of leaf area index, which is the main component of biomass

511 production modules (Heuvelink, 1999; Marcelis et al., 1998). It is however
512 generally considered as constant, although it has been shown, for instance
513 on wheat (Rawson et al., 1987), that SLA varies according to genotypes,
514 leaf ranks and leaf growing periods. Regarding sunflower, the variations of
515 SLA and the factors influencing them are still poorly known. As SUNLAB
516 can simulate dynamics of individual blade mass profiles independently from
517 those of blade areas, the SLA can be computed as a model output, contrary
518 to the classical situation where it is taken as input. In Fig.7, the simulated
519 and observed values for individual blade areas and masses of “Melody” in
520 the “2001” dataset are displayed for each blade rank and six different growth
521 stages.

522 [Figure 7 about here.]

523 The SLA was computed at the time when individual blades have reached
524 their highest mass on 67th day. SLAs are illustrated for blades ranking from
525 9 to 15 which are those whose individual blade mass and area had the best
526 accordance to the field data (Fig. 7). The root mean squared error (RMSE)
527 of SLA for these blades ranking from 9 to 15 was 11 and the coefficient of
528 variation (CV) was 25%. But for all blades on 67th day, including those
529 whose individual blade leaf areas were poorly simulated, the RMSE of SLA
530 for genotype Melody became 35, with CV value 76%. The computed SLA
531 showed some variability among the four genotypes. But since the current
532 SUNLAB parameters came from reconstructed individual blade masses, these
533 simulated SLA results are expected to be improved with better experimental
534 data in the future. Moreover, the modeling of individual leaf area should be
535 improved as well for more accuracy on this result.

536 4. Discussion and conclusion

537 *Models in the breeding process.* After further tests and improvements, this
538 new SUNLAB model should present robust enough predictive capacities and
539 ability to differentiate between genotypes in order to be proposed as a proper
540 tool for the understanding of crop phenotypes induced by genotype $\times$ en-
541 vironment interactions. Practical considerations should also be examined
542 in our context of model application, *i.e.* transferring model-based informa-
543 tion to breeders. This kind of information could be for instance recommen-
544 dations on optimal environmental conditions or management practices for
545 a given genotype; the identification of particular features (a subset of the
546 model parameters, for instance) to focus on in the breeding process in order
547 to create variants with some targeted traits; environmental characterization
548 for genotypes performances; or the prediction of crop growth and harvest.

549 SUNLAB has the potential to be used in studying the link between crop
550 model parameters and genetic information. As stated in Messina et al.
551 (2006), the breeding of higher-yielding crop plants would be greatly accel-
552 erated if the phenotypic consequences of changes at some genetic markers
553 of an organism could be reliably predicted. Recently, quantitative trait loci
554 (QTL) information has been incorporated into some organ-level crop models
555 (Reymond et al., 2003; Yin et al., 2006; Xu et al., 2011). To address the
556 link between model parameters and QTL, well designed models and suit-
557 able experimental data are required. Appropriate model structures allow
558 sufficient physiological feedback features to be incorporated. Model input
559 parameters should be designed to be grounded potentially in gene-level un-
560 derstanding (Yin et al., 2004). It requires the plant growth model parameters

561 having biological meaning to represent genetic coefficients (Yin and Struik,
562 2010; Tardieu, 2003). The organ-level model SUNLAB and its parameters
563 are expected to meet the requirements. In line with what has been done
564 for pepper in Alimi et al. (2013), SUNLAB is considered to be used in a
565 study with an experimental database of 90 sunflower genotypes which are
566 F1 hybrid of the first filial generation resulting from a cross mating of $9 \times$
567 10 distinctly different parental types. After estimating SUNLAB parameters
568 for the 90 genotypes, statistical analyses of the correlations between different
569 genotypes' parameters could reveal certain genetic links.

570 *About the modeling approach: from process-based model to functional struc-*
571 *tural model.* The design of the SUNLAB model was based on an ecophys-
572 iological model, SUNFLO, that was transformed to a FSPM and enriched
573 with a mechanistic module for biomass allocation to organs. Fenni: in the
574 deleted paragraph “While there exist many excellent PBM models with ac-
575 curate model identification and growth description, it is possible to convert
576 them into FSPMs to take advantage of FSPMs' structures and organs' in-
577 teraction, and to reduce the efforts of building a FSPM from blank. Feng
578 et al. (2010) tested using GREENLAB sink-source solver to improve the PBM
579 model PILOTE (Mailhol et al., 1997) for the crop Maize (*Zea mays* L.) Ac-
580 tually, these previous sentences were already re-used below.. In this paper,
581 SUNLAB is a good demonstration for the crop Sunflower (*Helianthus an-*
582 *nuus* L.). It defines sunflower's structural development and it adds complex
583 biomass partitioning mechanism to SUNFLO, while it keeps certain modules
584 of this PBM model, with the advantages of inheriting its ecophysiological
585 merits...”, some sentences were actually trying to answer the first reviewer's

question in the previous review: “ A simple conceptual representation could be useful to better understand how the source-sink model (GREENLAB) integrates with process-based model (SUNFLO)”. Do you think we should add some more sentences as the conceptual representation of the integration of FSPM module in SUNLAB?Vero: I am not sure, but I think that what the reviewer meant was that we add a figure with a diagramm of the SUNLAB model, don’t you think so? If so, anyway, we have not done it. In process-based models (PBM), plants are usually considered only at the level of organ compartments. Turning them into FSPM allows taking advantage of the simulation of individual organs’ growth and of interactions between organogenesis and functioning. FSPMs focuses on the development, growth and function of individual cells, tissues, organs and plants in their spatial and temporal contexts (Godin and Sinoquet, 2005). It is a solution to take into account the plant’s architectural development and to extrapolate PBM at organ level by merging the botanical knowledge on plant development with the functional equations (de Reffye et al., 2008). Introducing a mechanism of trophic competition at organ level in a PBM, as done in this study, opens the possibility to model feedbacks effects of biomass partitioning on other processes such as photosynthesis or organogenesis (Mathieu et al., 2009).

A more classical way to construct FSPM consists in integrating functioning processes into an existing architectural model. This was done for instance for trees in the AMAP- suite (Barczi et al., 2008), for grappevine in Pallas et al. (2011) based on the relationships defined for organogenesis in Lebon et al. (2004), or for wheat in Evers et al. (2010) who built a FSPM from the ADEL-wheat model. Once plant architecture is simulated, incorporating

functional processes arise as a natural subsequent step in model development. In particular, these 3D-mock-ups are often used to compute light interception. In contrast, since SUNLAB originates from a PBM, the emphasis is put on modeling plant functioning, phenology and effects of water and thermal stresses, while light interception is modeled in a rather simplistic way not relying on the exact 3D structure. A similar approach was applied for the development of the Ecomeristem model of rice growth (Luquet et al., 2006) that incorporates some features (carbon supply, simulation of an initial carbon reserve pool and the mobilisable fraction thereof) of a simple crop model SARRA-H (Dingkuhn et al., 2003). Feng et al. (2010) also tested using the GREENLAB sink-source solver to improve the PBM model PILOTE (Mailhol et al., 1997) for the crop Maize (*Zea mays* L.).

Generally, our approach fits into a current general trend of development of modular models, with generic modules that can be shared by other modelers. This trend goes hand in hand with the increasing number of modeling platforms: Pygmalion in our case (Cournède et al., 2013), OpenAlea (Pradal et al., 2004), GroIMP (Kniemeyer et al., 2006), etc. These platforms provide flexible frameworks for the coupling of models or the re-use of modules in different models. It reduces the efforts of building models from blank and mutualizes the implementation work. SUNLAB falls within that trend since most of its modules are generic and could be easily adapted to other crops (e.g. biomass allocation module, biomass production module, water budget,...).

Mechanistic modeling and empirical modeling. SUNLAB is the fruit of an effort to make the SUNFLO model more mechanistic (through the modeling of

636 biomass partitioning). Mechanistic models generally arise from approaches
637 relating to the complex system theory: they consider the individual com-
638 ponents of the system and their interactions, and what emergent properties
639 appear. They have the potential to be used out of their calibration inter-
640 val, provided that the model predictive capacities have been preliminarily
641 checked. In contrast, empirical models are derived on direct descriptions of
642 observed data. They are usually regression based and provide a quantitative
643 summary of the observed relationships among a set of measured variables.
644 Most plant growth models combine in fact both modeling approaches as a
645 mixture of mechanistic modules and empirical modules.

646 It is expected that mechanistic description of ecophysiological processes
647 improves the model predictive capacities and their ability to differentiate be-
648 tween genotypes (Allen et al., 2005; Minchin and Lacointe, 2005; Bertheloot
649 et al., 2011). However, the extent to which more mechanistic models are
650 necessarily better should be questioned. In particular, since the parameters
651 in mechanistic modules are assumed to have assigned biological meanings
652 and to represent properties of real system components, the reliability of the
653 underlying assumptions need to be carefully validated. I kept this sentence,
654 but I am not sure of what you meant, Fenni. Could you explain me? Fenni:
655 because the mechanistic models normally try to simulate the biological hy-
656 pothesis, the parameters in mechanistic modules have assigned biological
657 meanings. Therefore, it need more scrutiny to determine whether the hy-
658 pothesis and the biological meanings are true. I got this sentence from this
659 article: Biomedical Applications of Computer Modeling, Chapter 7.2 Em-
660 pirical or mechanisticvro: ok. Do you agree with the way I modified the

661 previous sentence, then?. Thus, the appropriateness of mechanistic models
662 needs close scrutiny (Christopoulos and Michael, 2000). Moreover, the pa-
663 rameterization effort of these more and more complex models should always
664 be taken into account when improving their mechanistic description, to pre-
665 vent from a high level of uncertainty in the parameters which may hinder the
666 original purposes of the model in terms of prediction and genotypic differen-
667 tiation. So, as stated in the introduction, a delicate trade-off has to be found
668 between mechanistic aspects and complexity, in order to provide proper tools
669 that might be used in the breeding context.

670 *Parameter estimation issue: direct measurements and model inversion.* Two
671 kinds of methods were involved for SUNLAB parameterization: estima-
672 tion through direct measurements and estimation through statistical meth-
673 ods, sometimes referenced as model inversion methods. Direct measurement
674 method enables direct access to the desired parameter via experimental mea-
675 surements (Jeuffroy et al., 2006). The model inversion method, involving
676 mathematical and statistical calculations, estimates one or more parame-
677 ters by confronting observed data to simulation results (Guo et al., 2006;
678 Cournede et al., 2011).

679 Direct measurement is used to estimate parameters that have biological
680 meanings, and that can be directly observable or easily calculated from mea-
681 sured indicators. Parameters with biological meanings consist of two types:
682 “genotypic parameters” which differ between varieties and “crop parameters”
683 which are parameters with small variance among all genotypes. Theoretically,
684 direct measurement method is the best for estimating genotypic parameters
685 and consequently for genotype characterization. The breeder could measure

686 it directly on lines under development in experiments in order to predict the
687 expected effects (Reymond, 2001). Similarly crop parameters can be mea-
688 sured directly from field data. Because of the direct and accurate measures on
689 elementary processes, these estimated parameters have advantages in terms
690 of ecophysiological relevance, parameter accuracy and genotype characteriza-
691 tion, compared with model inversion method. This perspective has led to au-
692 tomated and high-throughput advanced plant phenotyping (see for example
693 Granier et al. (2005), Sotirios and Christos (2009)). However, the accurate
694 elementary processes do not necessarily imply that the combination of these
695 processes will provide the same accuracy at plant scale. The nonlinear in-
696 teractions between processes as well as the necessary simplifications in terms
697 of the number of ecophysiological processes considered in the model make
698 the whole plant model not a simple combination of the elementary models
699 that were well calibrated by experiments: plants are complex systems whose
700 description of elementary process interactions, plasticity and robustness re-
701 mains an open issue (Yin and Struik, 2010). Therefore, parameterization
702 methods relying on model inversion to estimate parameters from experimen-
703 tal data at organ or whole plant levels offers an alternative. This method can
704 ensure an optimized fitting error on training data, but the prediction error
705 on validation data has to be carefully checked to avoid over-fitting problems.
706 The parameters thus obtained have the risk to be less relevant for their bio-
707 logical meanings than direct measurement, because these parameters values
708 may be altered by the error compensation from fitting whole plant processes
709 and from other simultaneously estimated parameters (Jeuffroy et al., 2006).
710 They nevertheless characterize the plant global behavior and may still be

711 used to differentiate between genotypes (Letort, 2008).

712 When parameter estimation is demanded for a high number of genotypes,
713 direct measurement method becomes impractical, because this method often
714 requires specific trials and measurements, which are complicated, costly and
715 even impossible to implement sometimes (Reymond, 2001). Routine mea-
716 surement of these parameters for a large number of varieties may also pose
717 a problem, particularly when measurements require special equipment and
718 controlled condition experiments (Jeuffroy et al., 2006). Model inversion
719 method is adopted for these cases because it is experimentally less costly
720 and less time-consuming. For instance in most dynamic models, the direct
721 measurement method would often require frequent measurement points (e.g.
722 daily), while with the indirect method, data can be collected only at some
723 given time points and still allow the modellers to retrieve the past growth of
724 the crop. Parameters can even be estimated from very limited sets of data
725 (Kang et al., 2011).

726 Moreover, some parameters are “hidden”, i.e. cannot be experimentally
727 measured and can only be estimated by model inversion method. They usu-
728 ally appear in mechanistic modules, because their underlying mechanisms
729 can produce emergent properties that can be difficult to disentangle *a pos-*
730 *teriori* from the resulting phenotype. It also implies that, because of their
731 interactions, these kinds of parameters cannot be obtained independently
732 from each other: the whole estimation process needs to be performed on all
733 the data at the same time (it is not possible to optimize sequentially on data
734 for different types of organs, for instance).

735 In SUNLAB, the parameters inherited from SUNFLO have biological

736 meaning and had been measured for 20 genotypes. Meanwhile, the param-
737 eters involved in the new biomass allocation module are hidden parameters
738 that can only be estimated by model inversion, because the biomass alloca-
739 tion process at organ level is difficult to observe and to be directly measured.

740 *Limitations and perspectives*

741 *Modeling.* From the model performances results, we can see that the mod-
742 eling of blade area needs to be uppermost improved in SUNLAB. A first
743 improvement could consist in replacing the use of the logistic function by a
744 fully mechanistic approach including modeling the SLA instead of deriving it
745 *a posteriori* from the simulated mass and areas. Thereby, feedbacks effects of
746 trophic competition on leaf area expansion could be explored and modeled.

747 The biomass accumulation module was directly inherited from SUNFLO
748 that has been tested in different environmental conditions for 26 genotypes
749 (Casadebaig et al., 2011; Lecoeur et al., 2011) and is in line with what is classi-
750 cally done in models of the same class as SUNLAB (e.g. Tomsim (Heuvelink,
751 1999), Ecomeristem (Luquet et al., 2006)). A more detailed approach, at
752 individual leaf level, could be considered by computing the amount of inter-
753 cepted radiations: several methods are available (e.g. Nested Radiosity light
754 model in Evers et al. (2010) or a Monte-Carlo radiation model in Xu et al.
755 (2011)) but they require an accurate modeling of the plant structure which is
756 currently not available and would necessitate additional experimental work
757 to be parameterized. It has to be noted that SUNLAB is not *stricto-sensu* a
758 FSPM since no 3D shape is simulated.

759 As regards the biomass distribution module that was introduced in our
760 study, our approach is based on the concept of common pool of assimilates

761 and relative sink competition. However, some other models (e.g. ECOPHYS
762 [Lacointe et al., 2002])) and experimental observations (Pallas et al. (2008))
763 suggest that the distance from source to sink could have an influence. An al-
764 ternative approach is thus to consider transport-resistance methods, as done
765 for instance in the L-PEACH model [Allen et al., 2005]: although these meth-
766 ods are biologically more relevant, they are generally complex and the result-
767 ing biomass distribution remains highly dependent on the determination of
768 sink activity. Bancal and Soltani [2002] compared the partitioning coeff-
769 cients obtained from an improved version of the transport-resistance model
770 of [Minchin et al., 1993] to the classical sink-based partitioning model: they
771 concluded that the resistance to flux propagation has an influence only in
772 pathologic cases of very low source activity and that resistance terms could
773 be abandoned in most cases as they are only a mathematical burden whose
774 parameter values are very difficult to measure experimentally. In our source-
775 sink approach, the main limiting factor is not the geometrical distance but
776 the topological organization of source and sinks (i.e. the number of other
777 sinks in a source-sink pathway) (Letort, 2008).

778 what do you mean exactly, with this solution?Fenni: I mean the feedback
779 effects of trophic competition on other plant functions could be simulated
780 in the future. It was written in the paragraph you deleted as such “How-
781 ever, the lack of trophic competition simulation may hinder the simulation of
782 feedback effects of biomass partitioning on other processes. As Pallas et al.
783 (2008) state, trophic competition influenced the organogenesis of grapevine
784 in their research. They suggest that a modeling approach simulating sink
785 strength variation and the local effects of sink proximity would be more rele-

786 vant than a model considering only development as a function of thermal time
787 or the global distribution of available biomass”. I tried to write the modeling
788 limitations in term of blade area modeling, and the modeling of feedback ef-
789 fects of trophic competition. Besides, the third reviewer asked in last review
790 “why the biomass accumulation is a very global level compared to the organ
791 level elsewhere. How do you justify these differences?” I answered him that
792 “The biomass accumulation module is directly inherited from SUNFLO while
793 the biomass distribution module is completely changed, as the first step of
794 adapting it into a FSPM model. Its performance and evaluation have shown
795 satisfactory results. Next step will be to add feedback effects of biomass
796 partitioning to the model, which will improve the simulation of morphogen-
797 esis, biomass production etc. This point is discussed in the Discussion and
798 conclusion session in this new version of paper”. Therefore I discussed here
799 why feedback effects need to be simulated. This is also my answer to the
800 first reviewer’s question “where is the biomass production’s under-estimation
801 from” and “why the upper leaves’ SLA can not be well simulated”. I put
802 the reasons to the bad simulation of blade area, especially the upper leaves’
803 blade area. I mentioned some improvements of biomass production modeling
804 can be planned in the future, such as the feedback effects of biomass distribu-
805 tion on blade area modeling, and also the consequent simulation of biomass
806 production. I also mentioned that to improve the simulation of SLA, “Be-
807 sides the approach that the logistic function, which is used to model leaf area
808 in SUNLAB, can be compared with other functions, the feedback effect of
809 trophic competition on leaf area expansion can be investigated and modeled.”
810 So to sum up, with the limitation of blade area modeling, I tried to answer

811 reviewers' three questions: 1, why the biomass production is a very global
812 level compared with biomass distribution; 2, where is the under-estimation
813 of biomass production from; 3, why did we state that the SLA simulation of
814 upper leaves are not well simulated.

815 Fenni: the deleted sentences of leaf senescence “In SUNLAB, leaf senes-
816 cence is modeled to occur between phenology stages *M0* and *M3*. The
817 phenology timing “CTT(d)” is affected by water stress, which affects con-
818 sequently the rate of leaf senescence. Its leaf senescence start time can be
819 better modeled, since sunflower leaves senescence may occur before *M0* stage
820 in drought stressed conditions”, is actually an answer to the second reviewer’s
821 question in previous review: “Leaf senescence is in the model expected to
822 occur between the stages *M0* and *M3*. In the SUNLAB model, the impact
823 of the drought stress on the phenology is taken into account (page 6-line 54
824 to page 7-line 20); however this point should benefit to be discussed, as sun-
825 flower leaves senescence may occur before the *M0* stage in drought stressed
826 conditions”. I tried to mention the limit of leaf senescence modeling. Sunlab
827 doesn’t simulate leaf senescence in strong stress, occurring before *M0*. **Ok,**
828 **I put some back, then. Do you agree?** Besides, leaf senescence is currently
829 affected by water stress only (through the phenology timing “CTT(d)” that
830 affects consequently the rate of leaf senescence) and occurs between phenol-
831 ogy stages *M0* and *M3* while, in reality, it may occur before *M0* stage in
832 severe drought conditions. Therefore, the SUNLAB leaf senescence may need
833 also modifications and could include the effects of other environmental cues
834 such as day length and temperature, and various biotic and abiotic sources of
835 stress, that can affect the initiation and progress of leaf senescence (Aguera

836 et al., 2012).

837 *Sensitivity analysis.* The sensitivity analysis of SUNLAB model in this arti-
838 cle has provided parameters' accountability to the variance of crop yield and
839 revealed less than 15% of effects of parameter interactions in biomass dis-
840 tribution module. It suggests that for the simulation of yield, the empirical
841 modeling could be reasonable, i.e. calculating the yield without the con-
842 sideration of interactions between the capitulum and other organs' growth.
843 However, the dominant influence of capitulum's sink strength dynamics pa-
844 rameters $sinkA(cap)$ and $sinkB(cap)$ may indicate that a better harvest
845 function should be tested rather than a linear relationship with total dry
846 biomass. Sensitivity analysis could also be performed on other output of in-
847 terest such as blade area or stem biomass, in order to better understand the
848 respective influence of the input parameters on the different components of
849 plant phenotype. A sensitivity analysis considering all SUNLAB parameters,
850 rather than only parameters in biomass distribution, is also necessary to dis-
851 cover the potential interactions existing among all parameters and modules.
852 A limitation of the Sobol method that was used for these sensitivity analyses,
853 is that no correlations were included between the parameters, although they
854 might certainly exist. For example, the correlation analysis of these param-
855 eters based on our estimated values in a family of four genotypes indicates
856 a correlation factor of 0.8 for parameters $SR(petiole)$ and $SR(internode)$.
857 For the further characterization of genotypes, sensitivity techniques designed
858 for taking into account input parameters correlations should be adopted (Xu
859 and Gertner, 2007; Chastaing et al., 2012; Wu et al., 2013).

860 *Model parameterization and evaluation.* Once calibrated, SUNLAB was able
861 of reproducing phenotypic variabilities in different genotypic and environ-
862 ment experiments scenarios. The genotypes “Melody” and “Heliasol” (Fig. 3)
863 were shown to have better drought tolerance than the two other genotypes.
864 Their yields were hardly not influenced by water stress while the other two
865 experienced a slight reduction(around 15% of 2001 harvest). With some vari-
866 ation according to plant species, certain stages such as germination, seedling
867 or flowering are known to be the most critical stages, vulnerable to water
868 stress (Hadi et al., 2012). Seed germination is the first critical stage and
869 the most sensitive in the life cycle of plants (Ahmad et al., 2009) and seeds
870 exposed to unfavorable environmental conditions, such as water stress at this
871 stage may have seedling establishment compromised (Albuquerque and Car-
872 valho, 2003). However our simulation and field data suggested that drought
873 stress had little effect on crop growth. As sunflower is categorized as a low to
874 medium drought sensitive crop (Turhan and Baser, 2004), the water deficit
875 level might not be strong enough to cause severe growth deficits. An environ-
876 mental scenario with stronger water deficiency would be required to better
877 parameterize the model. Then, additional scenarios (more cultivar/lines or
878 different kinds of stress conditions) could either help further quantifying the
879 model predictive ability and the range of its validity conditions, or help iden-
880 tifying the inappropriate or missing modules that need further investigation.
881 More importantly, since the model parameters are numerically estimated,
882 these additional scenarios will also allow testing their stability under differ-
883 ent environmental conditions and using phenotyping data at different growth
884 stages (Ma et al., 2007, 2008). A good stability is a necessary condition to

885 consider these parameters as genotype-dependent and to move forward in-
886 vestigating their potential genetic determinism, as illustrated for example in
887 (Buck-Sorlin et al., 2005).

888 Fenni: Ok, I agree. This paragraph was added because of the first re-
889 viewer’s question “ Results from model evaluation are not really discussed.
890 I mean, all model are wrong but it is needed to discuss how suitable they
891 are for their use. e.g. Does improving the phenotyping (more cultivar/lines,
892 stress scenarios) automatically increase the prediction capacity when param-
893 eter are numerically estimated? Any insights on the actual model perfor-
894 mance for discriminating cultivars Vs working with lines?”. I didn’t answer
895 him about “discriminating cultivars” vs “working with lines”, because I don’t
896 know the answer. I think in our model, we don’t have parameters which can
897 discriminate lines. We only have genotypic parameters, which are cultivar-
898 dependant, and common parameters for all genotypes. He didn’t pose any
899 further question about this point in the new letter, but maybe you could add
900 something to answer his previous question. Ok, see above: I have added the
901 sentences from ”‘Then, additional scenarios...’’: do you agree?’’

902 *Conclusion: Summary of results.* A functional-structural model SUNLAB
903 was developed. It describes the sunflower topology and morphogenesis at
904 organ level with blades, petioles, internodes, and capitulum. Coordination
905 of the expansion dynamics of these organs is ruled by their initiation and
906 senescence thermal times. Ecophysiological processes interact with plant
907 structural dynamics to affect biomass accumulation and partitioning to or-
908 gans. As a joint concept of GREENLAB and SUNFLO models, SUNLAB
909 has better structural features than SUNFLO and it succeeds to deal with the

910 biomass distribution at organ level. SUNLAB inherits the ecophysiological
911 merits of SUNFLO that have been validated in different environmental con-
912 ditions for 26 genotypes (Casadebaig et al., 2011; Lecoeur et al., 2011). In
913 contrast, GREENLAB over-simplifies a number of processes, such as photo-
914 synthesis and assimilate conversion to biomass (Guo et al., 2006; Ma et al.,
915 2008), and it is still in its preliminary stage to include water source influence
916 and root system (Li et al., 2009). The ability of this newly-developed SUN-
917 LAB model to reproduce observed data of sunflower growth was evaluated
918 on four genotypes “Albena”, “Melody”, “Heliasol” and “Prodisol”.

1150 **List of Tables**

1151	1	Values of the main parameters inherited from SUNFLO. . . .	52
1152	2	Sensitivity analysis of SUNLAB parameters: first-order in-	
1153		dices of the most influential parameters (with index > 1%). . .	53
1154	3	Estimated parameter values of SUNLAB for four genotypes. .	54

Table 1: Values of the main parameters inherited from SUNFLO.

Parameter	Parameter values			
Name	Albena	Melody	Heliasol	Prodisol
E1 ($^{\circ}\text{Cd}$)	510	540	480	510
F1 ($^{\circ}\text{Cd}$)	900	920	880	900
M0 ($^{\circ}\text{Cd}$)	1160	1160	1150	1120
M3 ($^{\circ}\text{Cd}$)	1800	2060	1940	1840
Nmax (#)	31	26	24	25
A1 (cm^2)	9999	9380	8707	8233
A2 (#)	18.9	15.4	15.3	15.9
A3 (cm^2)	488	613	670	498
k (#)	0.78	0.96	0.88	0.87

Table 2: Sensitivity analysis of SUNLAB parameters: first-order indices of the most influential parameters (with index $> 1\%$).

sinkA(cap)	sinkB(cap)	sinkA(intern)	SR(cap)	SR(intern)	sinkB(intern)	internEpdTT
0.51	0.12	0.12	0.05	0.03	0.02	0.02

Table 3: Estimated parameter values of SUNLAB for four genotypes.

Parameter	Param. values <small>(with associated standard error)</small>			
Name	Albena	Melody	Heliasol	Prodisol
sinkA(blade)	8.4 <small>(0.22)</small>	2.8 <small>(0.12)</small>	2 <small>(0.1)</small>	4 <small>(0.16)</small>
