ABSTRACT

The existence of the ribose moiety in biomolecules poses two problems for prebiotic chemistry. First, the exclusive presence of the furanose isomer in RNA has to be accounted for since furanose is a minor form in solution and does not exist in crystals. Second, all D-ribose polymorphs are unstable in aqueous medium so that a stabilization mechanism has to be invoked. We observed that the adsorption on mineral surfaces as amorphous silica protects the sugar from degradation processes. Moreover, this silica surface, used as realistic chert model, is able to increase significantly the proportion of ribofuranose compared to ribopyranose forms. The interaction between surface and sugar was analyzed by ¹³C NMR. Our results show a very significant chemical and thermal stabilization of the adsorbed sugar by a silica surface and an almost twofold increase of ribofuranose compared to ribose in solution.

Mineral surfaces

Ribose, a simple sugar with the formula C₅H₁₀O₅, is a major component of the nucleotides that form RNA. In the context of prebiotic chemistry, its synthesis, stabilization, and chemical reactivity are particularly interesting, especially to assess the 'RNA World' hypothesis.¹

In this scenario, autocatalytic and informational RNA molecules are the first complex biopolymers to have emerged and provide a missing link between small molecules and living organisms. Even though interesting chemical pathways leading to the synthesis of nucleotides have been proposed that need not go through the free sugar,² it remains legitimate to wonder how the sugar component could have arisen. It could have been synthesized prebiotically by the formose reaction,³ based on the polymerization of formaldehyde and first evidenced by Butlerow in 1861, although as a rather minor product of this reaction.⁴ It is not enough to form ribose however, since a problem of isomer selection is encountered. Ribose presents four polymorphs, two with a pyranose and two with a furanose ring (scheme 1). Only the β-furanose form is used in RNA molecules. Moreover, D-ribose is unstable in solution. For example, at pH 9 and 60 °C, its half life is about 50 h; in more physiological conditions, at pH 7 and 37 °C, it should be around 500 h if one extrapolates from the data of Miller and co-workers.⁵ In the

solid state, the furanose form does not exist.⁶ Thus, two questions need to be answered: (i) how have the ribofuranose forms emerged and been selected to form RNA molecules; (ii) how has this sugar been stabilized in solution? A tentative answer to the second question is that borate complexes could have acted as ribose stabilizing agent.^{3,7} At least two studies have claimed that silicates in solution can also stabilize ribose during the formose reaction.⁸ Although this has not been observed in another experimental investigation,⁹ theoretical studies have confirmed that the ribose-silicate 2:1 complex is more stable than other pentose and hexose complexes, a concept experimentally verified by Lambert et al., and constituting a first example of selectivity of interaction between mineral centers and sugars.^{8a} Furthermore, theoretical results have also shown that silicate complexes should be formed exclusively with the furanose form because in the latter form, the HO-C-C-OH dihedral angle is sufficiently small to allow the formation of a planar five-membered ring^{8a} including the silicon atom, so that the silicate scenario could also help answer our question. (i) Since interaction with silicate is possible in solution, a third question can be asked: (iii) could silica or silicate surfaces have played a role in the emergence and stabilization of ribose and more specifically of ribofuranose? The influence of mineral surfaces on the formose reaction has been previously addressed.¹⁰ Montmorillonite, calcite, hydroxyapatite and alumina seem to promote the formation, in minor proportions, of unbranched aldoses. In these studies, no selectivity of condensation for specific ribose polymorphs was

Scheme 1. Ribose polymorphs.

observed. Of course, chemical analysis of minor products in a complex mixture is difficult and it seems necessary as a first step to analyze more precisely the interaction between monosaccharides and different mineral surfaces. In this respect, a few studies have analyzed the adsorption of ribose and nucleoside on clay mineral surfaces.¹¹ For example, Aisawa et al.^{11a} have adsorbed ribose on anionic clay minerals (LDH). The intercalation of ribose was observed in the interlayer space of clay, and it was claimed that the furanose form predominated, but the possible stabilization toward degradation was not discussed.

The present work focused on the interaction of ribose with an amorphous silica (SiO_2) with a high surface area ($380 \text{ m}^2/\text{g}$), Aerosil 380, and its relation to isomer selectivity and stability. Silica represents a possible model of mineral phases existing on the primitive earth such as cherts (microcrystalline silica-containing sedimentary rocks), and in addition organic species supported on it are easy to characterize.¹² We indeed observed that ribose confinement by adsorption on this surface significantly shifts the isomerization equilibrium to furanose and in addition stabilizes the adsorbed sugar against degradation.

1. Experimental

Ribose was provided by Sigma. Aerosil 380 (SiO_2) was provided by Evonik. It is a non-porous fumed silica with a BET surface area of $380 \text{ m}^2/\text{g}$.

1.1. Adsorption procedures

Ribose adsorption was carried out by impregnation or by selective adsorption methods. In the impregnation procedure, 300 mg of silica was wetted with a ribose solution (3.3 mL). The obtained paste was stirred at room temperature for 3 h and dried at 70°C in an oven. In the selective adsorption procedure, 300 mg of silica was dispersed in 25 mM ribose for 3 h at room temperature and stored at 70°C for 150 h at pH 9. The solid phase was separated from the liquid phase by centrifugation, and then dried at 30°C .

1.2. Analytical techniques

- ^{13}C NMR: HP-DEC sequences (proton high power decoupling) were recorded at room temperature with a Bruker Avance 300 spectrometer with a field of 11.8 T equipped with a 4 mm MAS probe with a spinning rate of 10 kHz. The pulse angle was 30° , decoupling was applied at 50 KHz, and the recycle time was 10 s. CP-MAS sequences were recorded at room temperature on the same apparatus. The contact time was $1000 \mu\text{s}$ (other values were tested as well, see [Supporting information](#)) The recycle time was 1 s for adsorbed ribose and 300 s for bulk ribose.

- TGA of the samples was carried out on a TA Instruments Waters LLC, with a SDT Q600 analyzer, using a heating rate $\tau = 5^\circ\text{C}/\text{min}$ under dry air flow (100 mL/min).

2. Results and discussion

TGA (thermogravimetric analysis) of bulk D-ribose shows an endothermic event without weight change at 90°C , due to ribose melting,¹³ followed by four weight-loss events (195°C , about 20%, endothermic; 280°C , weakly exothermic, and 320°C , strongly exothermic, 51%; and 510°C , around 29%, strongly exothermic and resulting in complete combustion; [Fig. 1](#) and [SI-Fig. 1](#)). Here we do not intend to discuss these events in detail but to use them as a fingerprint. The endothermic weight loss at the low temperature of 195°C could suggest ribose polymerization with water elimination, but complete linear polymerization would result in a 13% weight loss while the observed value is almost twice higher.

Since we were interested in ribose stability, we also left a 60 mM ribose solution to dry in an oven at 70°C (i.e., in the same conditions as used later for the preparation of ribose/silica, but without addition of any silica). The final product was a brown gel. This material had clearly undergone significant chemical modifications with respect to the starting ribose. Thus, its TG (see [Supporting information](#)) was totally different from that of ribose, and in particular did not show any melting transition at 95°C , indicating that the drying process had caused significant modifications in the ribose structure and confirming the well-known thermal instability of the latter molecule. The brown gel obtained from drying of the ribose solution at 70°C shows significant modifications in its ^{13}C solid-state NMR spectrum (see below), indicative of ribose degradation. New peaks appear at 107 ppm and below 100 ppm, corresponding to new carbon environments, and carbonyl environments appear at 180 ppm, probably corresponding to the linear form of the ribose.

Ribose was then adsorbed onto silica (with a 10 weight% loading, see [Section 1](#)), submitted to oven drying at 70°C , and its thermal reactivity investigated. Between 20°C and 110°C , a large amount of water was eliminated, indicating that the apparently dry sample actually contained no less than 32% weakly held water. Two broad thermal events were observed at higher temperatures: the first one with a $T_{\text{max}} = 185^\circ\text{C}$ is almost athermic and corre-

Figure 1. DTG (derivative of thermogravimetric signal) of bulk D-ribose (a), 10 weight% D-ribose on silica dried under air (b), the same dried under vacuum (c), the dried silica support (blank, d).

sponds to the loss of about 5% of the support weight; the second one, clearly exothermic, with a $T_{\max} = 308$ °C, corresponds to the loss of about 9% of the support weight (SI-Fig. 2). The total weight loss corresponds to the elimination of all the ribose (10%), plus a significant amount of rather strongly held hydration water. The significant temperature shifts as compared to bulk ribose reveal a specific interaction of the ribose molecules with the silica surface in the dry state.

One of the conclusions that may be drawn from these results is that ribose on silica, when dried under ambient air, retains a large amount of water—in fact enough water to dissolve the ribose to a 1.3 M solution. One could speak therefore of a supported solution or maybe a supported syrup.

We have attempted to dry the sample in more severe conditions, under vacuum at 50 °C. This resulted in a 15-fold reduction of weakly held water with respect to the air-dried sample: physically adsorbed water amounted in this case to only 3.0 molecules per nm², definitely below the monolayer, so that one no longer speaks of a supported solution phase. The higher-temperature part of the TG was very similar to that of the air-dried sample (compare Fig. 1c and b). Since the ribose is not in solution after vacuum drying, it could either be adsorbed on the surface or precipitated as a bulk phase. In fact X-ray diffractometry shows no bulk ribose peaks, be it after air-drying or vacuum drying. Therefore ribose can be molecularly adsorbed on the silica surface at least up to a loading of 10%w. On the basis of the silica surface area, such a loading corresponds to 1.05 molecules per nm².

In contrast to the brown gel obtained from drying the solution, the air-dried ribose/silica sample was white, and remained so even after drying under vacuum. This simple observation is not sufficient to establish that ribose is stabilized by its interaction with the surface; molecular-level information is needed. Figure 2 compares the solid-state ¹³C NMR spectra of bulk ribose, and the two ribose/silica samples. Table 1 lists the peak positions for these three samples, and also for the aqueous ribose solution used in the deposition procedure (liquid-state NMR).

Our data confirm that ¹³C NMR easily distinguishes between the four isomers of D-ribose. In the bulk solid, only the two pyranose forms were observed, while all four isomers were present in solution (two pyranose and two furanose isomers). The spectrum for bulk solid D-ribose is almost identical to the one reported in,⁶ and corresponds to a 2:1 mixture of the βp and αp isomers (with additional small splittings due to the existence of non-equivalent crystallographic positions).

Table 1

Chemical shifts (ppm) observed for ribose in solution, in the bulk and adsorbed onto silica

	Form	C1	C2	C3	C4	C5
Ribose aqueous solution	αp	92.8	69.4	68.6	66.7	62.3
	βp	93.1	70.3	68.3	66.5	62.3
	αf	95.1	70.2	69.3	82.3	60.6
	βf	100.0	74.0	69.7	81.8	61.7
Bulk ribose	αp	92.9	71.9	68.4	66.4	56.2
	βp	95.1	72.8	67.8	65.1	56.2
	αf	—	—	—	—	—
	βf	—	—	—	—	—
Ribose/SiO ₂ air-dried	αp	94.5	71.1	70.1	69.4	63.8
	βp	94.9	72.0	69.5	68.4	63.8
	αf	97.3	72.0	70.3	84.0	63.5
	βf	102.1	76.3	71.5	83.4	64.5
Ribose/SiO ₂ vacuum-dried	αp	94.4	72.6	71.1	68.5	62.2
	βp	95.3	72.6	71.1	68.5	62.2
	αf	97.2	72.6	71.1	84	58.1
	βf	102.4	75.6	71.1	83.5	62.2

For the air-dried ribose/silica, the NMR peaks are very sharp, more typical actually of liquid-state than of solid-state NMR. This is compatible with the idea that this sample contains a ‘supported solution’, as deduced from the TGA above, where the molecules retain a high mobility. In contrast, for vacuum-dried ribose/silica, the peaks are much broader but remain compatible with the chemical shifts of ribose, in contrast to the gel obtained from solution drying that was discussed above which indicated degradation products. In particular, no signal is observed in the carbonyl region, and so decyclization does not occur on silica-supported samples.

Thus, only ribose is present on the surface of silica, but in all four of its isomers. This is not surprising for the air-dried sample which shows the same speciation as a concentrated aqueous solution. However even for the air-dried sample, where the ribose molecules interact with the surface of the silica, ribose speciation remains significantly different from that in the bulk solid. In particular, the furanose forms are present; this can be stated with certainty in spite of the low resolution of the NMR spectrum, since the peaks of the αf and βf isomers are observed in a region (80–86 ppm) where there is no interference with other signals.

A more quantitative analysis of the NMR results can be provided based on the relative intensity of the C1 peaks. The corresponding ribose specifications are listed in Table 2; also provided for reference is the speciation in bulk liquid-state ribose, from Ref. 6.

Figure 2. Solid state ¹³C-CP-MAS NMR of bulk D-ribose, ¹³C-HPDEC NMR of air-dried ribose/SiO₂, and ¹³C-CP-MAS of ribose/SiO₂ dried under vacuum.

Table 2

Ribose isomer distribution (%) calculated from NMR spectra—C1 area

%	α_p	β_p	α_f	β_f
Ribose aqueous solution (liquid state NMR)	19	60	8	13
Liquid ribose, at melting point ⁶	25	46	12	17
Ribose/SiO ₂ air-dried	13	58	12	16
Ribose/SiO ₂ vacuum-dried	9	48	31	12

It can be seen that the air-dried ribose/silica contains a somewhat higher percentage of the furanose isomers than the solution used for deposition: 29.1% (12% α_f , 17% β_f) versus 21% (8% α_f , 13% β_f).

In the vacuum-dried sample, this proportion increases even more, to 43% furanose (31% α_f , 12% β_f). This estimate was obtained from a CP-MAS spectrum, which does not always allow easy quantification. However, we checked that the application of different contact times did not significantly modify the intensity ratios (see [Supplementary information, Fig. S5](#)), and besides the carbon atoms whose signals are used for quantification are in very similar chemical environments, compatible with similar polarization transfer dynamics.

When the sample is dehydrated, a direct interaction is probably established between ribose and the silica surface groups (mostly silanols). As shown in [Table 2](#), the strongest shift observed (about –6 ppm, assignment based on relative intensities) was for the C5 of the furanose form α_f . This is probably correlated with the establishment of a specific interaction between the surface and the C5 hydroxyl group of α furanose. This shift is of comparable magnitude, but of opposite sign to that observed for the same carbon in solution when iodide ions interact with ribose—an interaction that presumably does not involve the formation of covalent bonds.¹⁴ If one form is indeed selectively adsorbed on the silica surface, namely the α -furanose isomer, the speciation equilibrium should be displaced toward this form, as is indeed the case.

Finally, we wanted to determine if the stability enhancement of D-ribose by interaction with the surface could be extended to basic and alkaline conditions. A ribose solution at pH 9 (pH adjusted with NaOH) was stirred in the presence of Aerosil for 150 h at 70 °C and the dispersion was dried at 70 °C. The ¹³C NMR peak positions were the same as for ribose/silica (see [Supplementary information](#)), except for the C5 of α - and β -furanose that were shifted by about 1 ppm. No new carbon signals were observed, in particular no signal attributable to the carbonyl group was present at around 170 ppm.

According to Larralde et al.,⁵ the half-life of ribose in solution at pH 9 should be about 50 h at 70 °C, while our experiment lasted three times longer. The distribution between the ribose isomers in this case was: pyranose 69% (54.2% α_p , 14.4% β_p), furanose 31% (20.9% α_f , 10.5% β_f). These values are very similar to those of the ribose/silica sample discussed above.

3. Conclusion

The major result of our work is the stabilization of the D-ribose on the surface of silica, under drying and even under basic conditions. The adsorption and the drying process also significantly increase the proportion of furanose forms compared to ribose in solution. A more complete study on the physical chemistry of adsorbed ribose is underway taking into account the influence of cation complexation, and the relation of furanose and more specifically the β -D-ribofuranose selection with the formation of nucleobases and their subsequent phosphorylation.
