THE HOLOMORPHY CONJECTURE FOR IDEALS IN DIMENSION TWO

ANN LEMAHIEU AND LISE VAN PROEYEN

Abstract. The holomorphy conjecture predicts that the topological zeta function associated to a polynomial \( f \in \mathbb{C}[x_1, \ldots, x_n] \) and an integer \( d > 0 \) is holomorphic unless \( d \) divides the order of an eigenvalue of local monodromy of \( f \). In this note, we generalise the holomorphy conjecture to the setting of arbitrary ideals in \( \mathbb{C}[x_1, \ldots, x_n] \), and we prove it when \( n = 2 \).

0. Introduction

Let \( f \) be a complex polynomial. The topological zeta function associated to \( f \) and an integer \( d > 0 \) is a rational function on the complex line. It can be computed explicitly on an embedded resolution of singularities of \( f \). This expression yields a complete set of candidate poles for the topological zeta function, but many of these will not be actual poles, due to cancelations in the formula. This phenomenon would partially be explained by the monodromy conjecture and the holomorphy conjecture. The monodromy conjecture states that poles of the topological zeta function should give rise to eigenvalues of local monodromy of \( f \) (see [DL]). The conjecture we study in this note, the holomorphy conjecture, predicts that the topological zeta function is holomorphic unless \( d \) divides the order of an eigenvalue of local monodromy of \( f \) (see [V]). Both conjectures were motivated by similar conjectures about Igusa’s \( p \)-adic zeta function, due to Igusa (see [Ig]) and Denef (see [D2]), respectively.

In this article we introduce the holomorphy conjecture for ideals in \( \mathbb{C}[x_1, \ldots, x_n] \). The notion of embedded resolution is here replaced by the notion of log-principalisation of the ideal. In Section 2 we go on by providing some preliminary results in dimension 2 which we will use in Section 3 to prove the holomorphy conjectures for ideals in \( \mathbb{C}[x, y] \).

Date: April 18, 2011.

1. The holomorphy conjecture

Verdier introduced a notion of eigenvalues of monodromy for ideals, coinciding with the classical notion for principal ideals (see [Ver]). Based on this notion of Verdier, the second author and Véys gave a criterion à la A’Campo for being an eigenvalue of monodromy of a given ideal.

To recall this criterion, fix an ideal $I \subset \mathbb{C}[x_1, \ldots, x_n]$. Let $Y$ be the zero locus of $I$ in $X := \mathbb{C}^n$, containing the origin $0$. We construct the blowing-up $\pi : Bl_I X \to X$ of $X$ in $Y$ and we denote by $E$ the inverse image $\pi^{-1}(Y)$. Now consider a log-principalisation $\psi : \tilde{X} \to X$ of $I$ (the existence of that is guaranteed by Hironaka in [H]). This means that $\psi$ is a proper birational map from a nonsingular variety $\tilde{X}$ such that the total transform $IO_{\tilde{X}}$ is locally principal and moreover is the ideal of a simple normal crossings divisor. Let $\sum_{i \in S} N_i E_i$ denote this divisor, written in such a way that the $E_i, i \in S$, are the irreducible components occurring with multiplicity $N_i$. Let $\nu_i - 1$ be the multiplicity of $E_i$ in the divisor $\psi^*(dx_1 \wedge \cdots \wedge dx_n)$. The couples $(N_i, \nu_i), i \in S$, are called the numerical data of the log-principalisation $\psi$. For $I \subset S$, denote $E_I := \cap_{i \in I} E_i$ and $E_I^0 := E_I \setminus (\cup_{j \in S, j \notin I} E_j)$. We denote furthermore the topological Euler-Poincaré characteristic by $\chi(\cdot)$.

By the Universal Property of Blowing Up, there exists a unique morphism $\varphi$ that makes the following diagram commutative.

\[
\begin{array}{ccc}
\tilde{X} & \xrightarrow{\varphi} & Bl_I X \\
\downarrow{\psi} & & \downarrow{\pi} \\
X & & X
\end{array}
\]

**Theorem 1.** [VV2, Theorem 4.2] The number $\alpha$ is an eigenvalue of monodromy of $I$ if and only if there exists a point $e \in E$ such that $\alpha$ is a zero or pole of the function

\[
Z_{I,e}(t) = \prod_{j \in S} (1 - t^{N_j})^\chi(E_j^0 \cap \varphi^{-1}(e)).
\]

**Definition 2.** Let $\psi$ be a log-principalisation of $I$. The local topological zeta function at the point 0 associated to the ideal $I$ and the positive integer $d$ is the rational function in one complex variable

\[
Z_{d,\psi}^{(d)}(s) := \sum_{I \subset S \atop d \mid N_i} \chi(E_I^0 \cap \psi^{-1}(0)) \prod_{i \in I} \frac{1}{N_i s + \nu_i}.
\]
Proposition 3. The function $Z_{\text{top},\mathcal{I},\psi}^{(d)}$ does not depend on the choice of $\psi$.

Proof. The Weak Factorization Theorem (see [AKMW, §4]) assures that it is sufficient to check whether $Z_{\text{top},\mathcal{I},\psi}^{(d)}$ remains invariant when composing $\psi$ with a blowing-up with smooth centre having normal crossings with $\mathcal{I}\mathcal{O}_X$. We leave this as an easy exercice to the reader. $\square$

From now on we will write $Z_{\text{top},\mathcal{I}}^{(d)}$ for the local topological zeta function associated to $\mathcal{I}$ and $d$ at the origin. When $\mathcal{I}$ is principal, it coincides with the zeta function defined in [DL].

Conjecture 4. (Holomorphy Conjecture)

Let $d$ be a positive integer. If $d$ does not divide the order of any eigenvalue of monodromy associated to the ideal $\mathcal{I}$ in points of $\pi^{-1}\{0\}$, then $Z_{\text{top},\mathcal{I}}^{(d)}$ is holomorphic on the complex plane.

Note that $Z_{\text{top},\mathcal{I}}^{(d)}$ is holomorphic if and only if it is identically zero. The formulation we use is motivated by the analogy with Denef’s original $p$-adic version of the conjecture. When $\mathcal{I}$ is principal, this conjecture was formulated in [V, Remark 3.4]. For principal ideals in $\mathbb{C}[x,y]$, this conjecture has been shown by Veys in [V, Theorem 3.1]. Veys and the first author confirmed the conjecture for principal ideals in $\mathbb{C}[x,y,z]$ defining a surface that is general for a toric idealistic cluster (see [LV, Theorem 24]). In this article we will prove the holomorphy conjecture in the special case that $\mathcal{I}$ is an ideal in $\mathbb{C}[x,y]$. The structure of our proof is inspired by the structure of the proof in [V].

2. Preliminary results

From now on, we put $X = \mathbb{A}^2_\mathbb{C}$ and we consider a finitely generated ideal $\mathcal{I}$ in $\mathbb{C}[x,y]$. We fix once and for all a set of generators for $\mathcal{I}$, say $f_1, \ldots, f_r$, and a log-principalisation $\psi : \tilde{X} \to X$ of $\mathcal{I}$. Notice that $\psi$ also gives an (non-minimal) embedded resolution for all elements of some Zariski open subset of the linear system $\{\lambda_1 f_1 + \cdots + \lambda_r f_r = 0 \mid \lambda_1, \ldots, \lambda_r \in \mathbb{C}\}$. We will call these elements totally general for $(f_1, \ldots, f_r)$. Moreover, the numerical data associated to the principalisation and to the embedded resolution are the same. A proof of this statement can be found in [VV1, §2]. Let us write $\mathcal{I}$ as $\mathcal{I} = (h)(f'_1, \ldots, f'_r)$ with $(f'_1, \ldots, f'_r)$ finitely supported. We fix a principalisation for $(f'_1, \ldots, f'_r)$ and we will say that a totally general element for $(f'_1, \ldots, f'_r)$ with respect to the chosen principalisation is general for $\mathcal{I}$. We will use the notation introduced in Section 1. In particular the $E_i, i \in S$, will be the irreducible components of $\mathcal{I}\mathcal{O}_X$. We choose a totally general element $f$ for $\mathcal{I}$ and we can write
\[
\psi^{-1}(f^{-1}\{0\}) = \sum_{i \in T} N_i E_i, \text{ with } T \text{ a set containing } S. \text{ Let } k_i, i \in S, \text{ be the number of intersection points of } E_i \text{ with other components of } \psi^{-1}\mathcal{I}. \text{ Analogously, for } i \in T, \text{ let } k'_i \text{ be the number of intersection points of } E_i \text{ with other components of } \psi^{-1}(f^{-1}\{0\}). \text{ So } k_i \leq k'_i \text{ for } i \in S, \text{ with equality if and only if } E_i \text{ is not intersected by the strict transform of a general element for } \mathcal{I}.
\]

If \( \mathcal{I} \) has components of codimension one, we can write the total transform as a product of two principal ideals: the support of the first one is the exceptional locus, where the support of the second one is formed by the irreducible components of the total transform that are not contained in the exceptional locus. This second ideal is the weak transform of \( \mathcal{I} \).

We will use the following congruence.

**Lemma 5.** [L, Lemme II.2] If we fix one exceptional curve \( E_i \), intersecting \( k'_i \) times other components \( E_1, \ldots, E_{k'_i} \) of \( \psi^{-1}(f^{-1}\{0\}) \), then \( \sum_{j=1}^{k'_i} N_j \equiv 0 \mod N_i \).

Veys shows the following result in his proof for the holomorphy conjecture for plane curves. He proved this for the minimal embedded resolution, but the proof remains valid for non-minimal resolutions induced by log-principalisations.

**Lemma 6.** [V, Lemma 2.3] Let \( E_0 \) be an exceptional curve with \( k'_0 = 1 \). Then for some \( r \geq 1 \) there exists a unique path

\[
\cdots \longleftrightarrow \quad E_0 - E_1 - E_2 - \cdots - E_r
\]

in the resolution graph consisting entirely of exceptional curves, such that

1. \( k'_j = k_j = 2 \) for \( j = 1, \ldots, r - 1 \);
2. \( k'_r \geq 3 \);
3. \( N_0 | N_j \) for all \( j = 1, \ldots, r \);
4. \( N_0 < N_1 < \cdots < N_r \).

We will now provide a set of eigenvalues of monodromy. Let \( n : Bl_{\mathcal{I}X} \to Bl_{\mathcal{I}X} \) be the normalization map. Recall that the Rees components of an ideal \( \mathcal{I} \) are the irreducible components of the exceptional divisor on \( Bl_{\mathcal{I}X} \). Let \( \sigma : \tilde{X} \to Bl_{\mathcal{I}X} \) be such that \( \varphi = n \circ \sigma \). We will also call the corresponding exceptional components in \( \tilde{X} \) Rees components, so an exceptional component \( E \) in \( \tilde{X} \) is Rees if and only if \( \dim(\sigma(E)) = \dim(E) \). As the normalization map is a finite map, being contracted by \( \varphi \) is equivalent to being contracted by \( \sigma \). Theorem 1 gives us:

**Corollary 7.** If the exceptional component \( E_i \) in \( \tilde{X} \) is Rees for \( \mathcal{I} \), then all \( N_i \)th roots of unity are eigenvalues of monodromy.
We can recognize these Rees components in the resolution graph in a very easy way.

**Lemma 8.** An exceptional component $E$ on $\tilde{X}$ is contracted by the map $\varphi : \tilde{X} \to Bl_I \mathbb{C}^2$ if and only if the strict transform of a general element for $I$ does not intersect $E$.

**Proof.** Let $D$ be the Cartier divisor on $\tilde{X}$ such that $\mathcal{I}O_{\tilde{X}} = \mathcal{O}_{\tilde{X}}(-D)$ and let $F$ be the Cartier divisor on $Bl_I \mathbb{C}^2$ such that $\mathcal{I}O_{Bl_I \mathbb{C}^2} = \mathcal{O}_{Bl_I \mathbb{C}^2}(-F)$. Then by the projection formula one has $(-D) \cdot E = -\varphi^*(F) \cdot E = (-F) \cdot \varphi_* E$. Suppose $E$ is contracted by $\varphi$, then $\varphi_* E = 0$ and $(-D) \cdot E = 0$. If $E$ is not contracted by $\varphi$, then $\varphi_* E = k \varphi(E)$ for some strictly positive integer $k$. Since $-F$ is very ample relative to $X$, we have $-F \cdot \varphi(E) > 0$ and thus $(-D) \cdot E > 0$.

We now write $I = hI'$ with $I'$ an ideal of finite support. For a totally general element $f = hf'$ for $I$, we can write its total transform $\psi^{-1}(f^{-1}\{0\}) = D + S$, where $S$ is the strict transform of $f'$. By the projection formula, one always has that $(D + S) \cdot E = 0$.

Combining these formulas, one gets the statement of Lemma 8. □

**Proposition 9.** Let $E_j$ be an exceptional curve with $k_j \geq 3$. Then $N_j$ divides the order of an eigenvalue of monodromy of $I$.

**Proof.** If $E_j$ is Rees for $I$, then Corollary 7 yields exactly this result. Suppose now that $E_j$ is not Rees for $I$ and let $a$ be the point on the exceptional locus of $Bl_I \mathbb{C}^2$ such that $a = \varphi(E_j)$, where $\varphi : \tilde{X} \to Bl_I \mathbb{C}^2$. We define $S_a$ as the set of indices $i \in S$ which satisfy $\varphi(E_i) = a$.

By Theorem 1 it is enough to prove that

$$\sum_{i \in S, N_j \mid N_i} \chi(E_i^\circ) \neq 0.$$

It is given that $\chi(E_0^\circ) < 0$. We will now prove that every positive contribution to this sum is canceled by another negative contribution.

Suppose $\ell \in S_a$, $N_j \mid N_\ell$ and $\chi(E_\ell^\circ) > 0$. This means that $\chi(E_\ell^\circ) = 1$ and $k_\ell$ is equal to 1. If $k'_\ell \neq 1$, then by Lemma 8 $E_\ell$ is Rees for $I$ and $N_j$ is a divisor of the order of an eigenvalue of monodromy (Corollary 7). If $k'_\ell = 1$, then by Lemma 6 there exists a path with $k'_r \geq 3$.

If $E_r$ is Rees for $I$, Corollary 7 tells us that $e^{\frac{2\pi i}{N_r}}$ is an eigenvalue of monodromy and as $N_j \mid N_r$, also $N_j$ divides the order of it. Suppose now that $E_r$ is not Rees for $I$. By Lemma 8, $E_{\ell+1}, \ldots, E_r$ are not Rees and as $E_{\ell}, \ldots, E_r$ are connected, it follows that also $E_{\ell+1}, \ldots, E_r$ are contracted to the point $a$. As $E_r$ is not Rees, it follows by Lemma 8 that $k_r = k'_r$ and thus $\chi(E_0^\circ) < 0$. Now $N_j \mid N_\ell$ and by Lemma 6 $N_\ell \mid N_r$, 

\[ \begin{array}{cccc}
E_\ell & E_{\ell+1} & E_{\ell+2} & \cdots & E_r
\end{array} \]
so we have found a negative contribution canceling $\chi(E_i^r).

We now check whether there can exist two exceptional curves $E_\ell$ and $E_{\ell'}$ with $\varphi(E_\ell) = \varphi(E_{\ell'}) = a$, $\chi(E_\ell^r) = 1$, $N_j|N_\ell$ and $N_j|N_{\ell'}$, for which the respectively associated $E_r$ and $E_{r'}$ yielded by Lemma 6 are equal, such as illustrated in the figure below. By Property 4 of Lemma 6, we know that $E_r$ is created later in the principalisation process than $E_\ell, \ldots, E_{r-1}, E_{\ell'}, \ldots, E_{r'-1}$. So at the stage where $E_r$ is created, the resolution graph looks as follows.

Note that by the principalisation process it is impossible to have more than two exceptional curves intersecting $E_r$. We denote by $\tilde{E}$ the components of the strict transform of the curves that belong to the support of $I$. These components might be singular and are only present in the principalisation graph if $I$ is not finitely supported. Since the principalisation graph is connected, there are no other components at that moment. As $E_j$ is intersected at least three times, it follows that $E_j$ is equal to $E_r$ and if not, then by the general form of a resolution graph of a plane curve, it follows that $E_j$ is created later than $E_r$, what means $N_j \geq N_r$. By Lemma 6, $N_\ell < N_r$. This contradicts the assumption that $N_j|N_\ell$. □

3. Holomorphy conjecture for ideals in $\mathbb{C}[x, y]$

Now we prove the holomorphy conjecture for the local topological zeta function associated to an ideal in dimension two. Actually we are going to show that $Z_{top, I}^{(d)}$ is identically zero. The terminology ‘holomorphic’ has its origins in the context of $p$-adic Igusa zeta functions.

**Theorem 10.** Let $I$ be an ideal in $\mathbb{C}[x, y]$ and $\pi : Bl_I \mathbb{C}^2 \to \mathbb{C}^2$ be the blowing-up of $\mathbb{C}^2$ in the ideal $I$. Suppose $d$ is a positive integer that does not divide the order of any eigenvalue of monodromy associated to the ideal $I$ in points of $\pi^{-1}\{0\}$. Then $Z_{top, I}^{(d)}$ is identically 0 on the complex plane.

**Proof.** We search for components that contribute to the local topological zeta function. If $I$ is a principal ideal, then we refer to [V, Theorem 3.1].

Suppose that $E_i(N_i, \nu_i)$ is an exceptional component of the principalisation satisfying $d|N_i$. By Corollary 7 it follows that $E_i$ is not Rees for $I$ and thus $k_i = k_i'$. If $k_i \geq 3$, we use Proposition 9 to see that $d$ would be a divisor of the order of a monodromy eigenvalue. If $k_i' = 1$,
we use Lemma 6 to find an exceptional curve $E_r$ with $k_r' \geq 3$. If $k_r = k_r'$, we are again in the situation of Proposition 9. Since $d|N_i$ and $N_i|N_r$, this leads to a contradiction. If $k_r \neq k_r'$, the component $E_r$ is Rees for $\mathcal{I}$ and Corollary 7 brings the same conclusion. Hence, we obtain that having $d|N_i$ for an exceptional component $E_i(N_i, \nu_i)$ implies that $k_i = 2$.

Suppose now that $E_i(N_i, \nu_i)$ is a component of the support of the weak transform satisfying $d|N_i$. The only possible contribution of $E_i$ comes from an intersection point of $E_i$ with an exceptional component $E_j(N_j, \nu_j)$ for which $d|N_j$. By Corollary 7 it follows that $E_j$ is not Rees for $\mathcal{I}$. Then we showed that there exists exactly one other component $E_k$ that intersects $E_j$. From Lemma 5 it follows that $d|N_k$. If $E_k$ is Rees for $\mathcal{I}$, then we have a contradiction. If $E_k$ is a component of the support of the weak transform, then there is no Rees component in the principalisation graph. This implies that $\mathcal{I}$ is a principal ideal. If $E_k$ is exceptional and not Rees for $\mathcal{I}$, we can iterate this argument. By finiteness of the resolution graph we should once meet a component that is Rees for $\mathcal{I}$ or that is a component of the support of the weak transform. This has been discussed before.

The only contribution to the topological zeta function can come from an exceptional component $E_i$ with $\chi(E_i^o) = 0$. In particular, the contribution has to come from intersections with other exceptional components. Suppose that $E_j$ is a component that intersects $E_i$ and that $d|N_j$. Then $E_j$ must be exceptional. We do the same reasoning for $E_j$ and we find that $k_j$ must be two. Suppose $E_k$ is the other component that intersects $E_j$. By Lemma 5 we know that $d$ must divide $N_k$. We iterate this argument and get the existence of a component $E(N, \nu)$ that is Rees for $\mathcal{I}$ and for which $d|N$. This contradicts the choice of $d$ (Corollary 7) and so $d$ does not divide $N_j$.

We conclude that $Z_{\text{top}, \mathcal{I}}^{(d)} = 0$. □

**Example.** We consider the ideal $\mathcal{I} = (x^2y^4, x^{34}, y^6) \subset \mathbb{C}[x, y]$. A log-principalisation of $\mathcal{I}$ consists of eight successive blowing-ups. The intersection diagram with the numerical data can be found in the following figure. We use Theorem 1 to find the eigenvalues of monodromy. The exceptional curves $E_2, \ldots, E_7$ are contracted by the map $\varphi$ to the intersection point $a$ of the exceptional components $E$ and $E'$ in $Bl_{\mathcal{I}} \mathbb{C}^2$. The exceptional curves $E_1$ and $E_8$ are respectively mapped surjectively to $E$ and $E'$. As eigenvalues of monodromy we get the 6th roots of unity and the 34th roots of unity. For instance $d = 5$ is no divisor of the order of an eigenvalue of monodromy. The components $E_2$ and $E_7$ satisfy $\chi(E_2^o) = \chi(E_7^o) = 0$ and have an empty intersection. This implies that $Z_{\text{top}, \mathcal{I}}^{(5)}(s)$ is equal to zero. □
\[ E_2(10, 3) \quad E_5(22, 6) \quad E_6(26, 7) \]
\[ E_3(14, 4) \quad E_4(18, 5) \quad E_7(30, 8) \]
\[ E_8(34, 9) \]
