(i.e., mineral part of bone only) with different methods. At the organ level, the current and clinical reference method for measuring the amount of mineral in bone is by dual energy X-ray absorptiometry (DXA) which gives the so-called bone mineral density area (aBMD) [5, 6]. The term “area” comes from the fact that DXA is a two-dimensional method and thus only gives the bone mineral density per unit area (g.cm^{-2}). A three-dimensional measurement of the mineral density can be obtained by peripheral quantitative computed tomography (pQCT) [7, 8]. As a volumetric method, this measurement is called vBMD (for "bone mineral density volume") and is given in g.cm^{-3} . This measurement concerns only the zones of radius and tibia. At the tissue level, the main issue is to avoid any geometrical effect. Measuring only the mineral part is defined by the tissue mineral density parameter (TMD in g.cm^{-3}), which avoids the porosity, the vascular and canalicular network. TMD is obtained by high resolution pQCT and microcomputed tomography (μCT) but considers only the bone mineral part. In addition to other methods for measuring the mineral part of bone [9], quantitative microradiography allows to obtain the so-called degree of mineralization of bone (DMB in g.cm^{-3}), defined as the density of HA [10]. This well known and referenced technique is based on the radiographic acquisition of an embedded bone section of known thickness [11]. Since the method uses high resolution radiographic films, the spatial resolution is very high and the DMB obtained is very accurate. However, due to the disappearance of manufactured radiographic films, this technique needs to be updated using digital sensors.

The purpose of this study was to setup the upgrade of microradiography from high resolution radiographic films to a digital detector, and to quantify the image quality (in terms of contrast, noise and spatial resolution). After presenting the principle of DMB measurement, the specifications of the two systems are shown, as well as the corresponding calibration curves. Then the image quality obtained with the two systems was investigated to validate the replacement of the film by a digital detector.

2 Theoretical background for DMB measurement

When a monochromatic X-ray beam of N_0 photons of energy E irradiates a sample, the number of transmitted photons $N(E)$ follows the Beer-Lambert law (Eq. (1)).

$$N(E) = N_0(E) \cdot e^{-\frac{\mu(E, \rho, Z)}{\rho} \cdot \rho \cdot d} \quad (1)$$

where μ/ρ is the mass attenuation coefficient of the sample ($\text{cm}^2.\text{g}^{-1}$), Z its atomic number, ρ its density (g.cm^{-3}), and d its thickness (cm).

The Beer-Lambert law indicates that the global attenuation of an X-ray beam depends on its energy and material-dependent parameters, among which some are independent of energy (thickness and density), and one is energy dependent (μ/ρ).

The mass attenuation coefficient μ/ρ is introduced in the equation instead of the linear attenuation coefficient μ because it is independent from the density of the sample and, thus, on its physical state. μ/ρ values are well known for all simple chemical elements and can be computed for any compound, provided that its chemical composition is known.

The degree of mineralization of bone (DMB) is defined by the density of HA ρ_{HA} [12] and computed from the number of photons transmitted by a bone sample. With the incident flux being unknown, the measurement is based on a comparison with a reference object. Aluminum

(Al) was chosen as a reference because it is easy to use and perfectly known (thickness and density) [13].

The Beer-Lambert law applied respectively to Al and HA gives the following Eqs (2) and (3):

$$N_{AL}(E) = N_0(E) \cdot e^{-\left(\frac{\mu(E, \rho, Z)}{\rho}\right)_{AL} \cdot \rho_{AL} \cdot d_{AL}} \quad (2)$$

$$N_{HA}(E) = N_0(E) \cdot e^{-\left(\frac{\mu(E, \rho, Z)}{\rho}\right)_{HA} \cdot \rho_{HA} \cdot d_{HA}} \quad (3)$$

Eqs (2) and (3) show that the number of photons transmitted by the Al or bone sample is related to thickness and density. In our case, the unknown parameter is bone mineral density (ρ_{HA}), while all others parameters are known. Thus, if the signals measured on bone and Al are identical, which means that $N_{AL}=N_{HA}$, considering the same incident flux N_0 , we get Eq. (4):

$$\left(\frac{\mu(E, \rho, Z)}{\rho}\right)_{HA} \cdot \rho_{HA} \cdot d_{HA} = \left(\frac{\mu(E, \rho, Z)}{\rho}\right)_{AL} \cdot \rho_{AL} \cdot d_{AL} \quad (4)$$

This allows us to link the DMB (ρ_{HA}) to the Al thickness d_{AL} (5):

$$DMB = \rho_{HA} = \frac{\left(\frac{\mu(E, \rho, Z)}{\rho}\right)_{AL} \cdot \rho_{AL} \cdot d_{AL}}{\left(\frac{\mu(E, \rho, Z)}{\rho}\right)_{HA} \cdot d_{HA}} = K \cdot d_{AL} \quad (5)$$

To apply Eq. (5), the K factor must be known. The density of Al is perfectly known (2.7 g/cm³), as well as the sample thickness d_{HA} (100 μ m). The mass attenuation coefficients of Al and HA depend on energy, and their values are tabulated [14]. The two curves of mass attenuation coefficients of Al and HA versus energy are shown in Fig. 1. For an energy of 8.05 keV, the ratio of mass attenuation coefficients is 0.571 and the K factor value is 0.571*2.7/0.01=1.54.

Fig. 1. Mass attenuation coefficients of aluminum (Al) and hydroxyapatite (HA) as a function of energy.

3 Specifications of the two systems using radiographic film and digital detector

As explained in the previous section, the DMB measurement depends on the energy. A monochromatic beam is preferred in order to compute the K factor (Eq. (5)). In practice, for the two systems, an X-ray tube is used with a copper anode (K_{α} radiation energy is 8.05 keV) and a nickel filter, like the very first studies of quantitative microradiography [13, 15]. The K-edge absorption of nickel is 8.3 keV, which is just above the K_{α} characteristic line of copper. Thus, the nickel filter is well adapted to attenuate energies just above the copper characteristic line. The spectrum obtained after filtration is still polychromatic, but with a strong preponderance of the copper characteristic line at 8.05 keV.

The two microradiographic systems are illustrated in Fig. 2. With the system using radiographic films, samples are directly in contact with the film. Thus, no magnification is used and no geometric unsharpness occurs. As a consequence, in contact microradiography, the focal spot size of the X-ray tube can be large, thus allowing a high radiation intensity.

On the contrary, with the digital detector, since the detector pixel size is higher than the desired spatial resolution, the magnification factor must be increased in order to obtain a smaller pixel size at the sample level. However, the geometrical unsharpness increases as well, and the use of a microfocus X-ray tube is required. The power is therefore reduced and the radiation intensity is low. A compromise needs to be found regarding image quality because a high intensity improves the signal to noise ratio (SNR), while increasing spatial resolution requires a decrease in intensity. This compromise will be discussed in section 5. The technical specifications of the two systems are summarized in Table 1.

Fig. 2. Microradiographic systems using (a) films and (b) digital detector.

Table 1. Technical specifications of both systems using radiographic films and a digital detector.

Features	System using radiographic films	Digital detector system
X-ray tube	X ray generator: Philips PW 1830/40 Diffraction tube: Philips PW 2273/20 Power maxi: 2.2 kW Cu anode, Ni filter Beryllium window: 300 μm Focal spot size: 4.2 mm ²	Microfocus Hamamatsu X-ray system L9421 -02 Power: maxi 8 W Cu anode, Ni filter Beryllium window: 150 μm Focal spot size: 5 μm diameter
Exposure parameters	High voltage: 25 kV Current: 25 mA Power: 625 W	High voltage: 40 kV Current: 50 μA Power: 2 W
Source to object distance	About 30 cm	Range: 1-25 cm
Object to detector distance	Contact	Range: 1-25 cm
Detector	Kodak radiographic films resolution: over 1000 pl/mm Revelator: Kodak D19 Fixator: Ilford Hypam Temperature: 20°C	Photonic science CCD camera FDI VHR 11M active area: 36x24 mm (4008 x 2671 pixels) scintillator: Gd ₂ O ₂ S:Tb filter Al: 12 μm
Image digitization step	Film digitized using a microscope coupled with a digital camera with 8 bits coding	12 bits digital image Detector pixel size: 9 μm Object pixel size depends on magnification factor.

4 Experimental validation using an Al step wedge

An Al step wedge was exposed using both techniques (8 regular steps from 12.5 μm to 100 μm). Typical grey-level profiles obtained by the two systems are shown in Fig. 3. Both profiles were normalized by their maximal value in order to be shown on the same scale. However, it is worth noting that the dynamic range of the detector is 4096 (12 bits), while 255 levels are available for the film system (8 bits).

For the digital detector system, the grey-level is proportional to the energy deposited in the detector, which is related to the energy transmitted by the object, weighted by the detector efficiency. Thus, a highest signal is obtained for small thicknesses where many photons are transmitted. For the other system (radiographic film coupled to a microscope), the deposited energy in the film increases its optical density (film darkening), and the obtained signal increases with Al thickness (which means when low energy is transmitted).

Fig. 3. Normalized grey levels obtained for an aluminum step wedge with both systems. M8 represents the thickest step and M1, the thinnest.

From the experimental evolution of the measured signals, we could deduce a logarithmic relation between Al thickness and grey levels, as given by Eq. (6):

$$d_{Al} = a \cdot \ln(GL) + b \quad (6)$$

where a and b are constant coefficients. In the case of the digital detector, the coefficient a is negative (when Al thickness increases, signal decreases and grey levels become black), and it

is positive in the case of radiographic film (the light intensity is measured through the radiographic film).

Finally, Eqs. (5) and (6) allowed us to obtain a relation between grey levels and DMB as follows:

$$DMB = a^* \cdot \ln(GL) + b^* \quad (7)$$

where $a^*=K.a$ and $b^*=K.b$. The obtained DMB as a function of grey levels is plotted in Fig. 4. This calibration curve allowed us to determine the DMBs for all possible values of grey levels in the range of interest.

For the system using radiographic films, the gain of the microscope camera was chosen in order to optimize the dynamic range in the domain of grey levels which were close to the bone tissue values. This is why five steps were used for the whole grey-level range.

The calibration was validated with the digital system by exposing a sample of 98% pure HA with a density of 3.08 g.cm^{-3} . The density calculated from the procedure was 3.015 g.cm^{-3} , i.e., a relative difference of 2.1%.

Fig. 4. Calibration curves of DMB as a function of grey-level, with film and digital detector.

5. Quantification of the image quality based on the contrast to noise ratio (CNR) and spatial resolution

5.1 CNR

The DMB is calculated from the grey-level. The smallest distinguishable DMB values are directly related to the grey-level contrast resolution. The noise level must be taken into account, especially for digital systems. An essential image quality parameter is the CNR. The CNR is defined as the grey-level difference between two thicknesses of a reference sample divided by the noise level [16]. CNR is given by the relation in Eq. (8):

$$CNR = \frac{|GL_1 - GL_2|}{\sqrt{\sigma_{GL_1}^2 + \sigma_{GL_2}^2}} \quad (8)$$

where: GL_i is the average grey level in zone i
 σ_{GL_i} the standard deviation of grey level in zone i .

A CNR of one means that the grey-level difference is equal to the noise level, i.e., the two thicknesses will be indiscernible. The higher the CNR, the better is the image quality in terms of contrast resolution. CNR increases when the contrast improves, which is known to be related to the energy of the X-ray beam: a low energy improves the contrast. On another hand, the CNR improves when the signal to noise ratio (SNR) improves, which is known to be related to the number of photons. Thus, the best quality should be obtained at a low energy and a high photon intensity. In our case, when increasing the high voltage, the mean energy of the spectrum increases, but the spectrum is still dominated by the copper characteristic line. A higher voltage increases also the total number of photons present in the spectrum, which increases the SNR. Overall, the CNR is better when increasing the high voltage.

In our study, CNR was calculated between two Al steps of 62.5 and 75 μm , since they corresponded to the closest values of DMB generally observed. In order to optimize the settings of the X-ray tube, we performed two tests: (1) the high voltage was changed while keeping a constant power of 2 W (which means that the intensity decreased when high voltage increased, keeping the same integration time of 7 s); and (2), high voltage was changed with a constant exposure of 0.35 $\mu\text{A.s}$ (which means the same intensity and integration time, but an increasing power). Fig. 5 shows that in both cases, CNR increased with high voltage, for the reason given above.

Fig. 5. Contrast to noise ratio as a function of high voltage either with a constant power (solid line) or constant exposure values (dotted line).

As a matter of comparison, CNR obtained with radiographic film was about 6.5 with an acquisition time of 20 min at 25 kV, 25 mA (optimized setting values for film [11]).

With regard to the digital system settings, a high voltage of 40 kV was selected (just before the maximal value of 45 kV). Concerning the current, our objective was to preserve the best spatial resolution (as the focal spot size increased with current), a low power had thus to be selected (2 W, i.e., 50 μA at 40 kV).

To maximize the flux of photon, it is possible to increase the detector integration time and average several images, at the expense of total acquisition time. Indeed, the CNR increases with the square root of the number of integrated images.

An average of 6 pictures was chosen here as a good compromise. All these parameters allowed to achieve a CNR of 5.5 which was acceptable, although less than the film CNR.

5.2 Spatial resolution

Spatial resolution measures the ability of a system to separate details which are close together. It is influenced by the resolution of the detector and by the geometric unsharpness which depends on the magnification factor and the focal spot size (the latter being related to the tube intensity). Following the Nyquist sampling theorem, a digital detector is able to discern an object whose size is at least greater than twice the size of a pixel. In our case, the detector pixels have a size of $9\text{ }\mu\text{m}$, thus the maximum intrinsic resolution (i.e. the resolution strictly due to the detector, without magnification and thus without geometric unsharpness) is expected to be $18\text{ }\mu\text{m}$.

A mean for estimating the spatial resolution is to calculate the modulation transfer function (MTF) of the system [17]. This is obtained using a regular edge object of high attenuation, and then to realize the Fourier transformation of the derivative curve profile. MTF curves for the film and the detector with different magnification are illustrated in Fig. 6. Using the digital detector, the closest line corresponding to the film system is obtained for a magnification of 3.7.

A useful criterion to compare several systems is to assess the spatial resolution limit as the one given for a certain MTF value, typically 10% [18]. For a magnification of 3.7, for instance, the spatial resolution limit is 100 lp/mm , i.e., $5\text{ }\mu\text{m}$. At this magnification level, the object pixel size is $2.43\text{ }\mu\text{m}$ (detector pixel size divided by the magnification factor), which means a Nyquist value of 4.86, in good agreement with the result, indicating that resolution is limited by pixel size and not by the scintillator effect.

Fig. 6. Modulation transfer function curves obtained for several magnifications M with digital detector (full lines) compared to film (dashed line).

The use of a calibration bar-space pattern (gold bars engraved in a plastic sheet) is another way to determine and verify the spatial resolution of the system. The contrast transfer function (CTF) is a plot of the contrast obtained versus the spatial frequency. The procedure of measurement is

represented in Fig. 7: from the image of the reference object, a grey-level profile is extracted and allows computing the contrast obtained for each spatial frequency. CTF is always above the MTF because it corresponds to a rectangular pattern, while by definition the MTF corresponds to a sinusoidal one.

CTF curves obtained for different magnifications with the digital system (full lines) and with radiographic film (dashed line) are shown in Fig. 7(c). This confirms that a magnification of 4 is necessary with the digital system to correspond with film.

It must be noted that the spatial frequency is limited to 20 lp/mm due to the minimal bar-space of the pattern which is 25 μm , and thus the curve cannot be plotted above this value.

Fig. 7. Calculation of the contrast transfer functions (CTF). (a) image of the bar space pattern, (b) the corresponding grey-level profile and (c) CTF curves obtained for film and digital detector with different magnifications.

Given the MTF, the CTF can be also determined by the Coltman formula [19] with the use of Eq. (9):

$$C(f) = \frac{4}{\pi} \left(M(f) - \frac{M(3f)}{3} + \frac{M(5f)}{5} - \frac{M(7f)}{7} + \frac{M(9f)}{9} - \frac{M(11f)}{11} + \dots \right) \quad (9)$$

where, $M(f)$ = sine wave MTF

$C(f)$ = bar target CTF

f = spatial frequency.

The CTF values are in agreement with the MTF values using this relation.

5.3 Comparison of an image obtained by the two systems on the same bone sample

Fig. 8 shows images performed with the two systems on an identical bone sample (Fig. 8(a)). For the digital system, two images were taken: one with a magnification of 3.7 (Fig. 8(c)) and another with the maximum magnification 10.8 (Fig. 8(d)). With the magnification of 3.7, the system allowed to obtain overall the same structures than with the radiographic film (Fig. 8(b)), but the image was less sharp. With the magnification of 10.8, the picture obtained was very similar to the radiographic film. For the three configurations, the grey-level profiles were plotted along two similar bone structures and they were very similar (Fig. 8(e)). CNR obtained with radiographic film and with digital detector (M=3.7 and M=10.8) were respectively 8.2, 7.1 and 7.9.

Fig. 8. (a) Comparison of microradiographs of a human iliac bone biopsy and zoom of a specific part of the image obtained with (b) the radiographic film and with the digital system at two different magnifications: (c) 3.7 and (d) 10.8. (e) Curves representing the grey-level profiles obtained respectively on the images (b), (c) and (d) across two bone specific units.

6 Conclusion

The digital system provides a good CNR (about 5.5 on the range referred DMB with conditions specified above). Moving the sample holder allows adjusting the magnification between 1.6 and 10.8 and this allows to achieve a similar spatial resolution compared to film for a magnification factor of 4. A higher magnification allows to achieve an even better MTF than film. Final images on bone samples show the same level of detail between film and digital detector at the highest magnification factor (10.8). On the other hand, the digital system dynamic range is 12 bits (i.e., 4096 values) versus 8 bits (255 values) for system using films. So the grey level information is more precise with the digital system. Finally, acquisition settings have been fixed as mentioned in Table 2.

Table 2
Acquisition settings for digital system

Parameter	Value
High voltage (kV)	40
Current (μ A)	50
Acquisition time (s)	7
Number of frames	6
Magnification factor	10.8

The use of a digital detector for radiographic imaging has the advantage of being easier to use than films. Indeed, film chemical revelation can be modified by temperature, user manipulation and fixator time settings. Moreover, there is no consumable anymore. We can also mention the problem of reciprocity of films: the efficiency of a digital detector is linear with exposition, but with the film, the efficiency decreases with exposition. This phenomenon is known as the Schwarzschild effect [20]. So with the digital system, we can easier control the evolution of photon flux when exposure time is modified compared to a system with radiographic films. Another point with the two systems is the fact that several images are required to cover the entire sample, especially when the magnification factor is higher. Thus, the total acquisition time will depend of number of images required. For a sample which needs 12 images, for instance, about 8 min are necessary against 20 for the entire sample with the radiographic film. In conclusion, the two systems have similar performances with regard to image quality (CNR and spatial resolution). The digital system has the advantage of being easier to use than the system with films, with lower acquisition times. The use of a digital detector has been validated regarding the image quality necessary for characterization of bone mineralization. The next step concerns validation of quantitative assessment of bone mineralization variables as mean DMB, heterogeneity index. These variables will be measured and compared between the two systems for several bone specific units from the same human bone samples.
